ARTICLE INFO

ABSTRACT

We delineate a general framework for incorporating many types of micro data from summary statistics to full surveys of selected consumers into Berry, Levinsohn, and Pakes (1995)-style estimates of differentiated products demand systems. We extend recommended practices for BLP estimation in Conlon and Gortmaker (2020) to the case with micro data and implement them in our open-source package PyBLP. Monte Carlo experiments and empirical examples suggest that incorporating micro data can substantially improve the finite sample performance of the BLP estimator, particularly when using well-targeted summary statistics or "optimal micro moments" that we derive and show how to compute.

If Python is installed on your computer, PyBLP can be installed with the following command:

```
pip install pyblp
```

Up-to-date documentation for the package is available at https://pyblp.readthedocs.io.

1. Introduction

Estimating supply and demand for differentiated products is a fundamental empirical challenge for a wide range of economic questions. Nearly thirty years ago, Berry et al. (1995) developed a class of estimators that allow for both flexible substitution patterns and endogenous prices. A key feature of the BLP approach is that it requires only "aggregate data" on prices and total sales of products at the market level, and exploits cross-market variation in prices, demographics, and product assortment in order to estimate flexible substitution patterns (Berry and Haile, 2014).

In many cases, researchers also have access to additional data on the decisions of individual consumers. These data may come from customer surveys (e.g., Maritz surveys recent automobile purchasers), or from tracking of individual purchasers (e.g., through

This table collects a non-exhaustive list of empirical papers that use the micro BLP estimator, along with the industry, country, and years for which each paper estimates demand. Some papers estimate demand for the listed broad industry and subsequently focus on a sub-industry. We only list published and recent working papers that do not diverge too much from the standard demand-side BLP model. In Table 3 we reorganize these papers by which micro moments they use.

loyalty cards or NielsenIQ panelists). These data are particularly useful when they link demographic information of individuals to characteristics of products, and when they contain information about the choices within individuals across time or product assortment. A growing literature has connected these "micro data" to the "aggregate data" of the classic BLP approach. Two prominent early examples of this "micro BLP" approach include Petrin (2002) and Berry et al. (2004a), and it has been used in a wide variety of applications, 29 of which we list in Table 1. The common feature of the micro BLP approach is a GMM estimator that augments the "aggregate BLP" moment conditions for demand (and optionally supply) with additional moments formed from micro data on individual purchases or survey responses.

Despite the popularity of incorporating micro data into BLP-style estimation, the literature lacks a standardized framework that is sufficiently general to encompass most use cases. Except for a few recent papers that use our software package,[1] most authors in Table 1 implement the BLP estimator on their own, use different notation, and extend the model to incorporate micro data in a problem-specific manner. This make replication difficult and the lack of corresponding formal econometric results makes it challenging to evaluate the statistical properties of micro BLP-style estimators. As an example, a key practical question is how one should weight the contributions of "aggregate data" versus "micro data" in the resulting estimator. Different choices may result in substantially different parameter estimates. One advantage of using a standardized framework is this guarantees that such decisions are made in a consistent way.

Along with delineating a standardized framework, we also systematize the types of "micro moments" that researchers can construct from "micro datasets". That is, one could attempt to match: (a) the correlation or covariance between price paid and income; (b) the average income of consumers who purchase particular products; (c) the average price paid for consumers of different income levels; or (d) the probability of purchasing certain cheap or expensive products for consumers of specific income levels. All of these moments are ways to measure similar features of the same joint distribution. Which moments researchers ultimately employ may largely be driven by convenience or necessity. Surveys tend to report a series of marginal distributions or "crosstabs" without providing the underlying individual responses, and industry reports (or other academic papers) may provide only simple summary statistics, instead of a complete dataset with individual choices. One issue we address is the extent to to which simple moments can

---

[1] Backus et al. (2021), Armitage and Pinter (2022), Calder-Wang and Kim (2024) and Conlon and Rao (2024) use our software package PyBLP to estimate micro BLP models. More papers use PyBLP to estimate BLP-style models with only aggregate data, but since our focus in this paper is on incorporating micro data, we do not collect a list of these other papers in this article.

approximate the information contained in a complete sample of individual decisions. In doing so, we also provide a characterization of the "optimal micro moments" in the spirit of Chamberlain (1987).

A second challenge, *compatibility*, arises when "aggregate data" and "micro data" are sampled from different populations or according to different sampling schemes (as in, e.g., Imbens and Lancaster, 1994). For example, researchers might have over a decade of purchase data on automobiles, but a consumer survey from only a single year. Alternatively, survey data may oversample individuals who are likely to purchase vehicles, suggest a different distribution of income than the overall population, or simply have variables that are measured differently than in the aggregated purchase data. In these cases, adding certain forms of micro moments may make estimates worse rather than better. Certain forms of micro moments may be more or less robust to these issues. Systematizing the types of micro moments researchers can construct allows us to be explicit about these challenges, and to discuss the pros and cons of different approaches to addressing them.

In our prior work, Conlon and Gortmaker (2020), we collected recommended practices for BLP-style estimation with aggregate data, and provided a common framework, PyBLP, which implements these recommended practices in an open-source Python package.[2] The goal of this article is to extend this earlier work to the case with micro data and make recommended techniques accessible to a wider range of researchers through PyBLP. For brevity's sake, we will refer to Conlon and Gortmaker (2020) whenever possible, particularly for more in-depth discussion of computation and simulation. In this article, after building up enough notation to define the aggregate BLP estimator in Section 2, we focus more on the applied econometrics that come with combining different sources of data into a single estimator.

Our work builds on a growing literature aimed at improving and better understanding the econometric properties of BLP-style estimation. Particularly important papers are Berry and Haile (2014, 2024), which develop a nonparametric framework for studying identification of BLP-style models using aggregate and micro data. Complementary to nonparametric results, in Section 3 we rely on economists' intuition from linear IV problems and econometric results in Salanié and Wolak (2022) to illustrate when aggregate data may be insufficient to accurately estimate key demand parameters. In Section 7 we run Monte Carlo experiments to describe how nonparametric identification results translate to finite samples.

A key contribution of this article is to delineate a standardized econometric framework for how to incorporate many different types of micro data into BLP-style estimation. In Section 4 we characterize micro datasets as information from statistically independent surveys of potentially selected consumers. Conditional on aggregate data (product characteristics and underlying demographic distributions), a survey administrator selects a finite set of underlying consumers with known sampling probabilities. Information from the resulting dataset (consumer choices and demographics) can be incorporated into estimation by adding "micro moments", which match observed statistics with their model counterparts.

In Section 5 we demonstrate how the framework considered in this paper encompasses essentially the same micro moments used by the prior literature (and described in Table 1).[3] In Section 8, we provide a more in-depth empirical example estimating demand for soft drinks with NielsenIQ data. For estimating parameters that govern how consumers with different demographics value different product characteristics, we point to micro moments that contain information about the covariance between demographics and product characteristics. For estimating parameters that govern the degree of unobserved preference heterogeneity, we point to second choice data about what consumers would have chosen had their first choice been unavailable (as in, e.g., Berry et al., 2004a).

The framework we consider, however, is more general, and supports matching many different statistics computed from surveys with many forms of selection. Our goal is to cover most empirical use-cases, including using all the information in a micro sample. Supported statistics include smooth functions of sample means, including correlations and regression coefficients. Underlying samples of consumers can be selected based on their market, demographics, or even endogenous product choices. Supporting general forms of choice-based sampling is particularly important because many surveys are targeted at consumers who have purchased certain products.

We derive asymptotic variances under different asymptotic thought experiments that show up in empirical work. This builds on Myojo and Kanazawa (2012), who extend the many products asymptotics of Berry et al. (2004b) to a specific type of micro moments originally used by Petrin (2002).[4] Although we do not attempt to provide a primitive set of conditions under which the micro BLP estimator is consistent and asymptotically normal, our Monte Carlo experiments in Section 7 indicate that the estimator has desirable asymptotic properties that translate to finite samples. With smooth micro moments, our analysis suggests that the estimator can perform well under many sizes of aggregate and micro data, particularly when there are many independent markets.

A potential concern is that the standard error estimators used by a number of papers, including Petrin (2002), require knowledge of the sample covariance matrix of micro summary statistics. Although a survey may report the average income by purchase group, it is unlikely to report the sample covariances between these averages. We show that knowledge of this additional information is not necessary for inference. Classical GMM estimation does not require that the researcher have a dataset with sample covariances between moments because these covariances can be estimated after obtaining a consistent estimator for the parameters. The same logic holds for micro moments. In Appendix E we derive analytic expressions for the asymptotic covariance matrix of a very broad class of micro moments, which allow researchers to form consistent standard error estimators with only the micro summary statistics

---

[2] We recommend installing PyBLP on top of an Anaconda distribution, which comes pre-packaged with PyBLP's primary dependencies. Users of other languages such as MATLAB, Julia, and R can use PyBLP with packages that allow for between-language interoperability (e.g., reticulate for R).

[3] In Appendix D, we show how using this framework, PyBLP estimates the model in Petrin (2002) with only a few lines of code.

[4] For the many markets case, Freyberger (2015) and Hong et al. (2021) study asymptotics for the aggregate BLP estimator. Grieco et al. (2023a) study many market asymptotics for their estimator which includes likelihood functions for the both the aggregate shares and micro data.

themselves and information about the number of underlying observations.

In addition to delineating a standardized framework for micro moments, in Section 6 we also contribute a characterization of the "optimal micro moments" and a simple procedure for computing them. In a best-case scenario when we observe and are willing to use all the results from a consumer survey that is fully compatible with the aggregate data, we can construct micro moments that match a consistent estimator of the average score function of the micro data. Along with consistent estimators of an optimal weighting matrix and Chamberlain's (1987) optimal instruments,[5] we show that the resulting estimator is statistically efficient within the class of all possible micro BLP estimators.[6]

Characterizing the optimal micro moments also allows us to explore what types of summary statistics researchers may wish to collect if unable or unwilling to use a full micro dataset in estimation. Inspecting the functional form of micro data scores provides intuition about why some standard micro moments in the literature perform particularly well, and why so-far unused micro moments can perform better. In Section 7's Monte Carlo experiments, we study the relative performance of standard, less-standard, and "optimal micro moments", while also pointing to recommended practices involving aggregate variation, pooling statistics across markets, and numerical integration.

In Section 8 we bring these recommended practices to a real-data example, in which we use NielsenIQ scanner and consumer survey data – two popular data sources in the industrial organization and marketing literatures – to estimate pre-2017 demand for soft drinks in Seattle. We then predict what would happen if prices increased by how much they did after the 2018 implementation of Seattle's sweetened beverage tax (SBT), and compare our substitution estimates to what actually happened. We expect that a structural approach to predicting policy effects is most useful in settings with limited reduced form evidence; however, we choose a SBT because we can compare our results with those from existing studies about the Seattle SBT.[7] We obtain similar results to what actually happened. Incorporating micro data allows us to break down our predictions by demographic group and achieve more realistic substitution patterns. Incorporating second choice data, which we show how to collect in a quick online survey, allows us to even better discipline substitution patterns, particularly to the outside good. By going through a full empirical exercise in detail, we hope to make clear what using the framework and recommendations considered in this paper looks like in practice.

Our work on optimal micro moments builds on literature that uses the likelihood of micro data in BLP-adjacent estimation, starting with Goolsbee and Petrin (2004) and Chintagunta and Dubé (2005). The standard approach in this literature is a two-step procedure: maximize the likelihood of the micro data and then run an IV regression of estimated mean utilities on product characteristics. Typically, researchers using micro BLP start with relatively complete aggregate data and add additional statistics taken from surveys or other sources, while researchers using such likelihood-based alternatives often start with the likelihood of relatively complete individual choices and augment this with second-stage moments from aggregate purchases. In contemporaneous work, Grieco et al. (2023a) propose a novel and efficient single-step estimator, which combines an individual likelihood, an aggregate data likelihood, and moments from aggregate demand.[8] Although a full review of likelihood-based approaches is beyond the scope of this guide for micro BLP estimation, we recommend that researchers try multiple approaches and carefully weigh the statistical and computational costs and benefits of each.

There is also a recent literature of alternative computational and statistical approaches to BLP problems which are beyond the scope of this paper. Dubé et al. (2012) propose an estimation algorithm for the aggregate BLP estimator based on the mathematical programming with equilibrium constraints (MPEC) method of Su and Judd (2012), which Conlon (2013) extends to generalized empirical likelihood (GEL) estimators. Lee and Seo (2015) provide an alternative estimator based on iterative approximations to the BLP problem (with aggregate data). Hong et al. (2021) propose implementing a Laplace-type estimator studied by Chernozhukov and Hong (2003) with Hamiltonian Monte Carlo.

In this article we follow Conlon and Gortmaker (2020) and focus on the more common nested-fixed-point approach to computation, which focuses primarily on the mixed logit. In Appendix B we discuss how our results extend to the random coefficients nested logit (RCNL) model of Brenkers and Verboven (2006). PyBLP fully supports the RCNL model, as well as an approximation to the pure characteristics model of Berry and Pakes (2007).

2. Aggregate data and estimation framework

In the left column of Table 2 we summarize the notation that we will introduce in this section. Throughout, we will use language that refers to consumers purchasing products in markets. However, the model is more general, and can be used to study different types of decision-makers choosing from various choice sets.

---

[5] In Conlon and Gortmaker (2020) we discuss optimal instruments at length and how to obtain computationally-cheap approximations to them, building on an original proposal by Berry et al. (1999).

[6] After defining relevant notation in Sections 2 and 4, we delineate this class more clearly in Section 6 and prove efficiency in Appendix F. It does not contain estimators that swap the (Berry et al., 1995) share constraint for a likelihood, such as the one proposed by Grieco et al. (2023a).

[7] For example, Powell and Leider (2020) uses a differences-in-differences approach, comparing with Portland, to measure price passthrough and substitution after the introduction of the tax.

[8] Grieco et al. (2023a) also provide a Julia package, Grumps.jl.

Table 2
Notation.

Notation for aggregate data and estimation (Section 2)		Notation for micro data and estimation (Section 4)	
$t \in \mathcal{T}$	Markets	$d \in \mathcal{D}$	Micro datasets
$\mathcal{M}_t \in \mathbb{R}_+$	Market size	$w_{dijt} \in [0,1]$	Sampling probability
		$w_{dijkt} \in [0,1]$	Joint sampling probability
$j \in \mathcal{J}_t$	Products		
$j = 0$	Outside alternative	$n \in \mathcal{N}_d$	Micro observations
$c = 1, \dots, C$	Observed product characteristics	$t_n \in \mathcal{T}$	Micro observation market
$m = 1, \dots, M_A$	Instruments	$i_n \in \mathcal{I}_{t_n}$	Micro observation type
$x_{cjt} \in \mathbb{R}$	Observed product characteristic	$j_n \in \mathcal{J}_{t_n} \cup \{0\}$	Micro observation choice
$x_{jt} \in \mathbb{R}^{C \times 1}$	All observed product characteristics	$k_n \in \mathcal{J}_{t_n} \cup \{0\} \setminus \{j_n\}$	Micro observation second choice
$z_{mjt} \in \mathbb{R}$	Instrument		
$z_{jt} \in \mathbb{R}^{M_A \times 1}$	All instruments	$p = 1, \dots, P_M$	Micro parts
$\xi_{jt} \in \mathbb{R}$	Mean-zero unobserved product quality	$d_p \in \mathcal{D}$	Micro part dataset
		$v_{pijt} \in \mathbb{R}$	Micro part value
$i \in \mathcal{I}_t$	Consumer types	$v_{pijkt} \in \mathbb{R}$	Second choice micro part value
$r = 1, \dots, R$	Consumer demographics		
$w_{it} \in [0,1]$	Consumer type share	$m = 1, \dots, M_M$	Micro moments
$y_{rit} \in \mathbb{R}$	Consumer demographic	$f_m : \mathbb{R}^{P_M \times 1} \to \mathbb{R}$	Micro moment function
$y_{it} \in \mathbb{R}^{R \times 1}$	All consumer demographics		
$v_{cit} \in \mathbb{R}$	Unobserved preference	$\overline{v}_p \in \mathbb{R}$	Micro part sample value
$v_{it} \in \mathbb{R}^{C \times 1}$	All unobserved preferences	$\overline{v} \in \mathbb{R}^{P_M \times 1}$	All micro part sample values
		$f_m(\overline{v}) \in \mathbb{R}$	Micro moment sample value
$u_{ijt} \in \mathbb{R}$	Indirect utility		
$\delta_{jt} \in \mathbb{R}$	Mean utility	$v_p(\theta) \in \mathbb{R}$	Micro part expected value
$\mu_{ijt} \in \mathbb{R}$	Heterogeneous utility	$v(\theta) \in \mathbb{R}^{P_M \times 1}$	All micro part expected values
$\varepsilon_{ijt} \in \mathbb{R}$	Idiosyncratic preference	$f_m(v(\theta)) \in \mathbb{R}$	Micro moment expected value
$s_{ijt} \in (0,1)$	Choice probability		
$s_{jt} \in (0,1)$	Market share	$s_{ijkt} \in (0,1)$	Joint choice probability
$S_{jt} \in (0,1)$	Observed market share	$s_{ik(-j)t} \in (0,1)$	Probability of choosing k without j
		$s_{ik-h(j)t} \in (0,1)$	The same, but without a group $h(j)$
$\beta \in \mathbb{R}^{C \times 1}$	Linear parameters		
$\Pi \in \mathbb{R}^{C \times R}$	Consumer demographic parameters	$M = M_A + M_M$	Number of combined moments
$\Sigma \in \mathbb{R}^{C \times C}$	Unobserved preference parameters	$\hat{g}(\theta) \in \mathbb{R}^{M \times 1}$	Combined sample moments
$\theta = (\beta, \Pi, \Sigma)$	All parameters	$\hat{W} \in \mathbb{R}^{M \times M}$	Combined weighting matrix
$N_A = \sum_{t \in \mathcal{T}} |\mathcal{J}_t|$	Number of aggregate observations	$N_d = |\mathcal{N}_d|$	Number of micro observations
$\hat{g}_A(\theta) \in \mathbb{R}^{M_A \times 1}$	Aggregate sample moments	$\hat{g}_M(\theta) \in \mathbb{R}^{M_M \times 1}$	Micro sample moments
$\hat{W}_A \in \mathbb{R}^{M_A \times M_A}$	Aggregate weighting matrix	$\hat{W}_M \in \mathbb{R}^{M_M \times M_M}$	Micro weighting matrix

This table summarizes the notation we introduce in Sections 2 and 4. Subscripts on parameters such as θ_0 refer to true values. Subscripts on operators such as $\mathbb{P}_A$ indicate conditioning on all aggregate data.

Aggregate data

Aggregate data are split into independent and identically distributed markets[9] that represent different realized choice sets for different consumers. Each market $t \in \mathcal{T}$ has a finite set of products $\mathcal{J}_t$, a finite set of consumer types $\mathcal{I}_t$, and a market size $\mathcal{M}_t \in \mathbb{R}$ that measures the mass of consumers in the market.

Each product $j \in \mathcal{J}_t$ has characteristics $(x_{jt}, z_{jt}, \xi_{jt})$. There are $c = 1, \dots, C$ observed characteristics $x_{jt} = (x_{1jt}, \dots, x_{Cjt})' \in \mathbb{R}^{C \times 1}$ that directly affect consumer demand. Typically, x_{jt} includes both exogenous characteristics, of which mean-zero unobserved quality $\xi_{jt} \in \mathbb{R}$ is mean-independent, and endogenous characteristics, such as price, which we expect to be correlated with ξ_{jt}. Instruments $z_{jt} = (z_{1jt}, \dots, z_{M_A jt})' \in \mathbb{R}^{M_A \times 1}$ include the exogenous characteristics in x_{jt} along with other exogenous observables and will be interacted with ξ_{jt} to form M_A moments from the aggregate data $\mathbb{E}[\xi_{jt} \cdot z_{jt}] = 0$.

In each market, there is a mass $\mathcal{M}_t$ of consumers. It is notationally convenient to split this mass up into discrete consumer types $i \in \mathcal{I}_t$. Each constitutes a known share $w_{it} \in [0,1]$ of consumers in the market, where $\sum_{i \in \mathcal{I}_t} w_{it} = 1$. Each consumer type has two sets of characteristics: $r = 1, \dots, R$ observed demographics $y_{it} = (y_{1it}, \dots, y_{Rit})' \in \mathbb{R}^{R \times 1}$ and $c = 1, \dots, C$ unobserved preferences $v_{it} = (v_{1it}, \dots, v_{Cit})' \in \mathbb{R}^{C \times 1}$ for the observed characteristics x_{jt}.[10] Typically, demographics y_{it} will be sampled from census data or some other representative survey and v_{it} will be sampled from a standard (potentially multivariate) normal distribution.

In the literature, i sometimes refers to individual consumers, rather than types of consumers. We focus on a discrete set of consumer types for notational convenience and practical relevance. In practice, most researchers use a fixed number of Monte Carlo draws from the distribution of demographics and unobserved preferences.[11] If the true distribution of consumer preferences

---

[9] This can be relaxed in standard ways to incorporate various forms of cross-market dependence, which can be accounted for with, for example, clustered standard errors. See Appendix E for more details.

[10] There will also be a third set of characteristics, idiosyncratic preferences ε_{ijt}, defined below. Unlike y_{it} and v_{it}, idiosyncratic preferences ε_{ijt} will differ among consumers of the same type.

is continuous, consumer types should be interpreted as a numerical approximation to this continuous distribution with integration weights w_{it}.

For brevity's sake, in this paper we do not discuss the econometric implications of simulation error resulting from only using a finite number of draws. Instead, in our Monte Carlo experiments and empirical example, we use recommended practices from Conlon and Gortmaker (2020), which involve either using a large number of scrambled Halton draws (Owen, 2017) or an appropriate quadrature rule, and do not account for simulation error when computing standard errors.[12]

In addition to differentiation by type $i \in \mathcal{I}_t$, the mass $\mathcal{M}_t$ of consumers is also differentiated by idiosyncratic preferences $\varepsilon_{ijt} \in \mathbb{R}$ for each product $j \in \mathcal{J}_t$ and the outside alternative, denoted $j = 0$. Indirect utility from selecting $j \in \mathcal{J}_t \cup \{0\}$ is[13]

$$u_{ijt} = \delta_{jt} + \mu_{ijt} + \varepsilon_{ijt}, \quad u_{i0t} = \varepsilon_{i0t}. \tag{1}$$

Mean utility $\delta_{jt} \in \mathbb{R}$ is common across consumer types and depends on product characteristics (x_{jt}, ξ_{jt}). Typically, an additivity assumption is made so that

$$\delta_{jt} = x'_{jt}\beta + \xi_{jt}. \tag{2}$$

The heterogeneous component of utility $\mu_{ijt} \in \mathbb{R}$ differs across types and will additionally depend on demographics and preferences (y_{it}, v_{it}). A popular functional form is

$$\mu_{ijt} = x'_{jt}(\Pi y_{it} + \Sigma v_{it}). \tag{3}$$

With normally distributed unobserved heterogeneity $v_{it} \sim N(0, I)$, indirect utility can be written as $u_{ijt} = x'_{jt}\beta_{it} + \varepsilon_{ijt}$ with random coefficients distributed $\beta_{it} \sim N(\beta + \Pi y_{it}, \Sigma\Sigma')$. We focus on this functional form because it is the most popular, but we also discuss three common variants, which are also supported by PyBLP. First, to guarantee downward sloping demand for all consumers, one can replace the random coefficient β_{cit} on price $x_{cjt} = p_{jt}$ with a lognormal random coefficient (see Appendix A). Second, to parsimoniously incorporate geographic distance or other important product-specific demographics y_{ijt}, one can replace interactions between product dummies in x_{jt} and demographics in y_{it} with y_{ijt}. Third, one can use other parametric distributions for v_{it}, such as exponential or χ^2 distributions.

Each consumer chooses among the discrete alternatives $j \in \mathcal{J}_t \cup \{0\}$ and selects the option that maximizes indirect utility. With type I extreme value idiosyncratic preferences ε_{ijt}, the logit probability that a consumer of type $i \in \mathcal{I}_t$ chooses a product $j \in \mathcal{J}_t$ is[14]

$$s_{ijt} = \frac{\exp(\delta_{jt} + \mu_{ijt})}{1 + \sum_{k \in \mathcal{J}_t} \exp(\delta_{kt} + \mu_{ikt})}. \tag{4}$$

Again, we focus on this distribution for ε_{ijt} because it is the most popular.[15] In Appendix B we discuss a common variant, which is to assume that ε_{ijt} follows the assumptions of a two-level nested logit. The resulting random coefficients nested logit (RCNL) model of Brenkers and Verboven (2006), is popular in applications where the most important product characteristic governing substitution is categorical.

Aggregate market shares are given by integrating over the mass of consumers. The mixed logit market share of product $j \in \mathcal{J}_t$ is

$$s_{jt} = \sum_{i \in \mathcal{I}_t} w_{it} \cdot s_{ijt}. \tag{5}$$

We use s_{jt} to refer to generic market shares, potentially evaluated at different parameters $s_{jt}(\theta)$. We use $S_{jt} = s_{jt}(\theta_0)$ to refer to the observed market shares generated by the true parameters θ_0.

The goal is to recover the true parameters $\theta_0 = (\beta_0, \Pi_0, \Sigma_0)$ that characterize the demand system. Since we will frequently refer to our earlier work, it is worth pointing out a difference in notation. In Conlon and Gortmaker (2020), we partitioned θ into three parts: θ_1 referred to the demand-side "linear parameters" β; θ_2, to the "nonlinear" parameters, which are typically (Π, Σ); and θ_3, to supply-side "linear" parameters.[16] Since our focus here is on the demand side, we use the notation $\theta = (\beta, \Pi, \Sigma)$, not $\theta = (\theta_1, \theta_2, \theta_3)$.

Toward recovering θ_0, the researcher first makes an assumption about how to define markets $t \in \mathcal{T}$ and their sizes $\mathcal{M}_t$. For each product, the researcher collects characteristics, instruments, and market shares: $\{(x_{jt}, z_{jt}, S_{jt})\}_{j \in \mathcal{J}_t}$. Typically, market shares are

---

[11] Simple Monte Carlo draws are equally-weighted, with $w_{it} = 1/|\mathcal{I}_t|$. Types may have different weights, for example, when demographics are sampled from a survey with sampling weights or when quadrature is used to approximate a continuous distribution. With certain types of quadrature such as sparse grid integration, weights w_{it} can be negative and may not sum to one. This can also happen with importance sampling.

[12] For those who are concerned about simulation error, PyBLP does support resampling consumer types to compute an estimate of the contribution of simulation error to the BLP or micro BLP estimator's asymptotic covariance matrix.

[13] Identification requires two normalizations. We follow standard practice by normalizing $\delta_{0t} = \mu_{i0t} = 0$. Levels of δ_{jt} and μ_{ijt} are then interpreted relative to those of the outside option.

[14] The one in the denominator is from the outside alternative normalization $\delta_{0t} = \mu_{i0t} = 0$.

[15] The pure characteristics model of Berry and Pakes (2007), which PyBLP can approximate (with approach (a) in Section 4.3 of the original paper), eliminates idiosyncratic preferences ε_{ijt} altogether. For a modern non-approximate algorithm for estimating the pure characteristics model, see Bonnet et al. (2022). Although our focus is on more tractable models with ε_{ijt}, incorporating micro data does allow for the estimation of more flexible models in which heterogeneous utility μ_{ijt} dominates, reducing dependence on ε_{ijt} that can otherwise contribute to unrealistic substitution patterns.

[16] With a supply side, the parameter in β on price becomes "nonlinear" in the sense that it needs to be optimized over, and would instead be in θ_2.

observed quantities divided by the assumed number of consumers in the market. A challenge in demand estimation is measuring this market size—in our empirical example in Section 8 we discuss how different market size assumptions can affect estimates and provide some recommendations. Finally, the researcher makes an assumption about consumer types: $\{(w_{it}, y_{it}, v_{it})\}_{i \in \mathcal{I}_t}$.

Aggregate BLP estimator

Since unobserved quality $\xi_{jt} \in \mathbb{R}$ is mean-zero and mean-independent of the M_A instruments z_{jt}, our assumptions about the aggregate data deliver M_A moment conditions $\mathbb{E}[\xi_{jt} \cdot z_{jt}] = 0$.[17] Using these, we can construct a GMM estimator for θ from $N_A = \sum_{t \in \mathcal{T}} |\mathcal{J}_t|$ aggregate observations and a weighting matrix $\hat{W}_A$ where hats denote sample approximations:[18]

$$\hat{\theta}_A = \underset{\theta}{\arg\min}\, \hat{g}_A(\theta)' \hat{W}_A \hat{g}_A(\theta), \quad \hat{g}_A(\theta) = \frac{1}{N_A} \sum_{t \in \mathcal{T}} \sum_{j \in \mathcal{J}_t} \underbrace{(\hat{\delta}_{jt}(\Pi, \Sigma) - x'_{jt}\beta)}_{\hat{\xi}_{jt}(\theta)} \cdot z_{jt}. \tag{6}$$

A key insight of Berry et al. (1995), building on Berry (1994), is that we can invert the demand system and recover δ_{jt} from $s_{jt}(\Pi, \Sigma, \delta_t)$ by matching the observed shares S_{jt}. In each market $t \in \mathcal{T}$, we can solve a system of $|\mathcal{J}_t|$ nonlinear equations to find the unique $|\mathcal{J}_t|$ mean utilities $\hat{\delta}_{jt}(\Pi, \Sigma)$ that equate observed market shares S_{jt} with their model counterparts:

$$S_{jt} = s_{jt}(\Pi, \Sigma, \hat{\delta}_t) \equiv \sum_{i \in \mathcal{I}_t} w_{it} \cdot \frac{\exp[\hat{\delta}_{jt} + x'_{jt}(\Pi y_{it} + \Sigma v_{it})]}{1 + \sum_{k \in \mathcal{J}_t} \exp[\hat{\delta}_{kt} + x'_{kt}(\Pi y_{it} + \Sigma v_{it})]}, \quad \forall j \in \mathcal{J}_t. \tag{7}$$

The econometric properties of this estimator under many products ("large J" asymptotics) are discussed in Berry et al. (2004b); many markets, in Freyberger (2015) and Hong et al. (2021).[19] In Conlon and Gortmaker (2020) we discuss recommended practices for this type of estimation and implement them as defaults in PyBLP: fast and stable algorithms for solving the inner problem for $\hat{\delta}_{jt}(\Pi, \Sigma)$ and the outer problem for $\hat{\theta}_A$, fast and accurate ways to integrate over consumer types $i \in \mathcal{I}_t$, robust solutions to various numerical challenges, and when appropriate, the use of fixed effect absorption and Chamberlain's (1987) optimal instruments. Throughout this article, we continue to use all of these recommended practices for the aggregate portion of estimation.

A common extension, which we discuss at length in Conlon and Gortmaker (2020), is to derive an additional set of aggregate moment conditions from the first-order pricing conditions of firms and to append the sample analogs of these moments to those in $\hat{g}_A(\theta)$. Especially when using an approximation to the optimal instruments, incorporating well-specified supply-side moments can substantially improve the performance of the aggregate estimator. However, in this article, we primarily focus on the demand-only model to highlight the contribution of micro data.[20]

3. Aggregate variation only

It can be difficult to flexibly estimate the nonlinear parameters (Π, Σ) governing heterogeneous tastes without substantial cross-market variation in product assortment (or prices), strong instruments, or a well-specified supply-side. This often forces researches to choose between a flexible demand system with poor econometric performance or a restricted demand system with unreasonable substitution patterns. In this section, we discuss the parametric identification of the aggregate model to motivate incorporating micro data, and propose some simple diagnostics.

Intuitively, identification of (Π, Σ) requires cross-market variation in demographic distributions and choice sets. For a fully nonparametric treatment of identification with aggregate, market-level data, see Berry and Haile (2014) or the summary in Section 5 of Berry and Haile (2021). Our experience is that a good starting point for understanding whether there is sufficient aggregate variation is intuition about linear IV regression models.

Intuition from linear regression

To leverage this intuition, we use results in Salanié and Wolak (2022), who approximate the aggregate estimator in Eq. (6) with a linear IV regression. There are pros and cons to using an approximate estimator discussed at length in Salanié and Wolak (2022), but for the purposes of this paper, we use it as a convenient source of intuition and quick checks on the data.

We write down the full approximation using this paper's notation in Appendix C but here consider only the simplest scalar case with $C = 1$ product characteristic, $R = 1$ demographic, and three parameters, $\theta = (\beta, \pi, \sigma)$. A second-order Taylor expansion around $\pi = \sigma = 0$ gives the following linear model with four regressors:[21]

$$\log \frac{s_{jt}}{s_{0t}} \approx \beta x_{jt} + \sigma^2 a_{jt} + \pi m_t^y x_{jt} + \pi^2 v_t^y a_{jt} + \xi_{jt}, \quad a_{jt} = \left(\frac{x_{jt}}{2} - \sum_{k \in \mathcal{J}_t} s_{kt} \cdot x_{kt} \right) \cdot x_{jt} \tag{8}$$

---

[17] It is common to assume $\mathbb{E}[\xi_{jt} \mid z_{jt}] = 0$ and convert these conditional moments into unconditional ones.

[18] Typically, we solve this problem twice. Once to obtain a consistent estimator for the optimal weighting matrix – and for the optimal instruments, if appropriate – and a second time to obtain the efficient estimator. The most common choice for the initial weighting matrix is the 2SLS weighting matrix, which would be efficient if ξ_{jt} were homoskedastic.

[19] In Appendix E we discuss both many products, $|\mathcal{J}_t| \to \infty$, and many markets, $|\mathcal{T}| \to \infty$.

[20] PyBLP supports combining micro and supply-side moments. We provide an example of this in Appendix D, where we use both to replicate (Petrin, 2002).

[21] Here, s_{0t} does not refer to a "true" share, like the true θ_0, but just the outside share for $j = 0$.

where $m_t^y = \sum_{i \in \mathcal{I}_t} w_{it} \cdot y_{it}$ is the within-market demographic mean, $v_t^y = \sum_{i \in \mathcal{I}_t} w_{it} \cdot (y_{it} - m_t^y)^2$ is its variance, and a_{jt} is an "artificial regressor" that reflects within-market differentiation of the product characteristic x_{jt}.[22] If $\pi = \sigma = 0$, the approximation is exact, and collapses to a familiar logit regression: $\log(s_{jt}/s_{0t}) = \delta_{jt} \equiv \beta x_{jt} + \xi_{jt}$.

The linear model in Eq. (8) is only an approximation, but its intuition about identification translates fairly well to the full model. First, without an instrument for the artificial regressor a_{jt} we should expect our estimate for σ^2 to be asymptotically biased—a_{jt} is a function of endogenous market shares s_{kt}, which are correlated with unobserved quality ξ_{jt}. Berry and Haile (2014) describe this problem as the "endogeneity of share" that needs to be addressed in the random coefficients model.[23] The "differentiation IVs" proposed by Gandhi and Houde (2020) and further evaluated in Conlon and Gortmaker (2020) look similar to a_{jt} and work well in practice compared to other types of "BLP instruments" that are functions of other products' exogenous characteristics.[24] Indeed, the first stage of an IV regression using differentiation IVs implements precisely the "IIA test" recommended by Gandhi and Houde (2020): estimate the simple logit regression controlling for differentiation IVs and consider a richer model if the IVs are statistically relevant.

Second, absent significant cross-market variation in assortment $\mathcal{J}_t$, the artificial regressor a_{jt} will be nearly collinear with x_{jt} and x_{jt}^2, and it will be difficult to separately identify σ^2 from β. This aligns with the standard intuition that with only aggregate data, the degree of unobserved preference heterogeneity, here measured by σ^2, is identified by how consumers substitute between products when faced with cross-market variation in choice sets.

Third, with only aggregate data, separate identification of (Π, Σ) requires cross-market variation in demographics y_{it}. If the distribution of y_{it}, here measured by its first two moments: mean m_t^y and variance v_t^y, does not vary much across markets, the regressors $m_t^y x_{jt}$ and $v_t^y a_{jt}$ will be nearly collinear with x_{jt} and a_{jt}, and it will be difficult to separately identify π and π^2 from β and σ^2. Absent cross-market variation in (m_t^y, v_t^y), distinctions between taste variation from demographics versus unobserved heterogeneity will be solely driven by functional form.

Even when using appropriate instruments, a lack of cross-market choice set and demographic variation will either result in poor estimators of (Π, Σ) or leave researchers with no alternative other than to estimate a more restrictive demand system. Supply restrictions aside, the typical solution is to exploit within-market variation from micro data that links demographics to individual choices, rather than aggregate market shares.

In practice, our recommendation when considering estimating a demand system with only aggregate data aligns with those of Salanié and Wolak (2022) and Gandhi and Houde (2020). We recommend first running a version of the IV regression in Eq. (8), with the full version written out in Appendix C, to get a sense of whether aggregate variation will be sufficient to estimate a flexible demand system.[25] If so, the estimates from this regression will give a sense of what reasonable starting values and parameter bounds may look like.

4. A standardized framework for micro data and estimation

In the right column of Table 2, we summarize additional notation that we will introduce in this section. We begin by explaining the notation and the framework we will use to characterize "micro datasets", indexed by d. We then build up additional notation to incorporate "micro moments" into the BLP estimator. "Micro moments", indexed by m, are smooth functions of "micro parts", indexed by p, which are in turn conditional expectations of scalar functions called "micro values".

Survey data

We begin with the assumption that micro data are split into datasets $d \in \mathcal{D}$ that report results from statistically independent consumer surveys. Statistically, micro data are generated conditional on all aggregate data: products $\mathcal{J}_t$, consumer types $\mathcal{I}_t$, and sizes $\mathcal{M}_t$ of all markets $t \in \mathcal{T}$.[26] We use the notation $\mathbb{P}_A$, $\mathbb{E}_A$, and $\mathbb{V}_A$ to denote probabilities, expectations, and variances conditional on all aggregate data.

Each consumer n is defined by a 3-tuple (t_n, i_n, j_n) and chooses $j \in \mathcal{J}_t \cup \{0\}$ with (mixed) logit choice probability $\mathbb{P}_A(j_n = j \mid t_n = t, i_n = i) = s_{ijt}$ following Eq. (4). Likewise, within each market, by construction the weight corresponding to each consumer type $i \in \mathcal{I}_t$ is the same as in the aggregate demand model Eq. (5), and is given by $\mathbb{P}_A(i_n = i \mid t_n = t) = w_{it}$. These types i and weights w_{it} include both observed demographics y_{it} and unobserved preferences v_{it}.

---

[22] Salanié and Wolak (2022) give additional intuition for the functional form of a_{jt}. A quadratic form is unsurprising because x_{jt} multiplies v_{it}. The $\frac{1}{2}$ comes from the symmetric shape of the logistic distribution.

[23] In a fully nonparametric model, a different instrument is needed for each of the $|\mathcal{J}_t|$ market shares (Berry and Haile, 2014).

[24] In Section 7 we use the "quadratic" version of differentiation IVs in our Monte Carlo experiments. For this example, differentiation IVs would be $z_{jt} = (x_{jt}, \hat{a}_{jt}, m_t^y x_{jt}, v_t^y \hat{a}_{jt})'$ where $\hat{a}_{jt} = \sum_{k \neq j} (x_{kt} - x_{jt})^2$. Expanded, $\hat{a}_{jt} = x_{jt}^2 - 2x_{jt} \sum_{k \neq j} x_{kt} + \sum_{k \neq j} x_{kt}^2$ and $a_{jt} = x_{jt}^2/2 - x_{jt} \sum_{k \neq j} s_{kt} x_{kt}$. The main difference is the share s_{kt}-weighted average of x_{kt} in a_{jt} instead of the unweighted average in $\hat{a}_{jt}$. Weighting by share is infeasible because market shares are endogenous. (This suggests a potential improvement upon the Gandhi and Houde (2020) IV which would be to construct $\hat{s}_{kt}$ as a function of exogenous variables.) The other difference is the "BLP instrument" $\sum_{k \neq j} x_{kt}^2$.

[25] With a reasonably small number of characteristics and demographics, is perhaps simplest to treat π^2 as an unconstrained fourth parameter, say γ, and to estimate π only from cross-market variation in demographic means m_t^y, while "controlling" for $v_t^y a_{jt}$.

[26] Depending on which asymptotic thought experiment from Appendix E is most appropriate, we may also include survey sampling probabilities, defined shortly, in the aggregate data.

However, not all consumers need be observed in a micro dataset. Instead, we assume that a survey administrator selects a finite set of consumers $n \in \mathcal{N}_d$ with independent sampling probabilities $\mathbb{P}_A(n \in \mathcal{N}_d \mid t_n = t, i_n = i, j_n = j) = w_{dijt}$. Most common survey designs can be represented with different sampling probabilities w_{dijt}, including stratification by the consumer's market, type, and even choice. For a survey to be useful, we need to know how it was conducted, so we will assume that the researcher knows the sampling probabilities w_{dijt} for each dataset $d \in \mathcal{D}$.

Consider some examples. If the survey randomly samples from all consumers in different markets, sampling probabilities should be proportional to the number of consumers in each market, $w_{dijt} \propto \mathcal{M}_t$. An alternative would be to stratify across markets so that consumers are sampled from each market with equal probability, $w_{dijt} \propto 1/|\mathcal{T}|$. Other common sampling schemes might only sample individuals conditional on making a purchase, $w_{dijt} \propto 1\{j \neq 0\}$, or on purchasing a particular brand b, with $w_{dijt} \propto 1\{j \in \mathcal{J}_b\}$. It is also common to sample individuals whose income y_{rit} is above or below some level (such as households eligible for WIC), for example $w_{dijt} \propto 1\{y_{rit} < \$50{,}000\}$. We can combine these into a more detailed example: $w_{dijt} \propto \mathcal{M}_t \cdot 1\{y_{rit} < \$50{,}000, t \in \mathcal{T}_d, j \neq 0\}$ would generate a random sample of consumers from a few markets $\mathcal{T}_d \subset \mathcal{T}$ with income below \$50,000 who make a purchase.

Micro statistics

Ideally, the researcher would observe a *complete* dataset of all sampled consumers' markets, choices, and demographics: $\{(t_n, j_n, y_{i_n t_n})\}_{n \in \mathcal{N}_d}$.[27] For example, the NielsenIQ panelist data tracks the products purchased by households, which stores they visit, and the demographics of the corresponding household. In this scenario, we can make full use of all the information in the micro dataset.[28] In many other cases, we will have incomplete data from a limited number of consumers, or summary statistics for subsets of individuals. The extent of our micro data will determine which "micro moments" we can and cannot compute.

We will use each micro summary statistic that we observe to define one of $m = 1, \ldots, M_M$ micro moments. Each micro moment m matches a single summary statistic, which could be a simple average, a weighted average, a conditional average, or even a covariance or regression coefficient.

Consider the following example. We are interested in capturing the relationship between having children and purchasing a minivan. Suppose we have access to summary statistics from a representative survey of households that purchased a car in $d = 2023$. Specifically, suppose we observe two summary statistics: the average number of kids across surveyed households, as well as the average number of kids across minivan purchasers,

$$\overline{\text{kids}}_{2023} = \frac{1}{N_{2023}} \sum_{n \in \mathcal{N}_{2023}} \text{kids}_{i_n t_n}, \tag{9}$$

$$\overline{\text{kids}}_{2023}^{\text{mini}} = \frac{\frac{1}{N_{2023}} \sum_{n \in \mathcal{N}_{2023}} \text{kids}_{i_n t_n} \cdot 1\{j_n \in \mathcal{J}_{\text{mini}}\}}{\frac{1}{N_{2023}} \sum_{n \in \mathcal{N}_{2023}} 1\{j_n \in \mathcal{J}_{\text{mini}}\}}. \tag{10}$$

We can use these two summary statistics to define $M_M = 2$ micro moments. The first, $\overline{\text{kids}}_{2023}$, is a simple average, and the second, $\overline{\text{kids}}_{2023}^{\text{mini}}$, is the ratio of two simple averages. To cover both of these cases (and many more), the framework we consider in this paper supports summary statistics that are smooth functions of simple averages.[29]

We call each simple average a "micro part". Each of the $p = 1, \ldots, P_M$ micro parts is an average over all $N_{d_p} = |\mathcal{N}_{d_p}|$ observations in its micro dataset $d_p \in \mathcal{D}$:

$$\overline{v}_p = \frac{1}{N_{d_p}} \sum_{n \in \mathcal{N}_{d_p}} v_{p i_n j_n t_n}. \tag{11}$$

Each part p is defined as the average of a function $v_p(t_n, j_n, y_{i_n t_n})$, or $v_{p i_n j_n t_n}$ for short, that may depend on the choice conditions (e.g., prices, assortment, and product characteristics) in the market t_n, the consumer demographics $y_{i_n t_n}$, and the selected choices j_n. The choice of $v_p(\cdot)$ is determined both by what statistics are available in our data, and which model parameters we are trying to estimate.

To match $\overline{\text{kids}}_{2023}$ and $\overline{\text{kids}}_{2023}^{\text{mini}}$, we will need to define $P_M = 3$ micro parts: the average number of kids in the micro data, the share of households who purchased a minivan, and the average number of kids multiplied by a dummy for purchasing a minivan,

$$\overline{v}_1 = \frac{1}{N_{2023}} \sum_{n \in \mathcal{N}_{2023}} v_{1 i_n j_n t_n}, \quad v_{1ijt} = \text{kids}_{it}, \tag{12}$$

$$\overline{v}_2 = \frac{1}{N_{2023}} \sum_{n \in \mathcal{N}_{2023}} v_{2 i_n j_n t_n}, \quad v_{2ijt} = 1\{j \in \mathcal{J}_{\text{mini}}\}, \tag{13}$$

$$\overline{v}_3 = \frac{1}{N_{2023}} \sum_{n \in \mathcal{N}_{2023}} v_{3 i_n j_n t_n}, \quad v_{3ijt} = \text{kids}_{it} \cdot 1\{j \in \mathcal{J}_{\text{mini}}\}. \tag{14}$$

---

[27] By definition, the researcher does not know unobserved preferences v_{it}.

[28] In Section 6 we discuss optimal micro moments that make full use of the information in a micro dataset. In Section 8 we demonstrate how to do so with NielsenIQ data.

[29] Below, we explain how to write weighted averages as simple averages using this same framework.

We have assumed that in the survey, we directly observe $\bar{v}_1 = \overline{\text{kids}}_{2023}$, but that we do not directly observe $\bar{v}_2$ or $\bar{v}_3$, only their ratio $\bar{v}_3/\bar{v}_2 = \overline{\text{kids}}_{2023}^{\text{mini}}$. To express the simple average $\overline{\text{kids}}_{2023}$, the ratio $\overline{\text{kids}}_{2023}^{\text{mini}}$, and any other smooth function of averages, such as covariances or even regression coefficients, we need to define slightly more notation.

Each micro moment m matches a scalar summary statistic denoted $f_m(\bar{v}) \in \mathbb{R}$, which is a smooth function $f_m : \mathbb{R}^{P_M \times 1} \to \mathbb{R}$ of potentially all micro moment parts $\bar{v} = (\bar{v}_1, \ldots, \bar{v}_{P_M})'$. In our example, our $M_M = 2$ two summary statistics can be written as

$$\overline{\text{kids}}_{2023} = f_1(\bar{v}) = \bar{v}_1, \tag{15}$$

$$\overline{\text{kids}}_{2023}^{\text{mini}} = f_2(\bar{v}) = \bar{v}_3/\bar{v}_2. \tag{16}$$

In general, each micro moment is defined by both its underlying micro values v_{pijt} and its smooth function $f_m(\cdot)$. We expect that most useful summary statistics are smooth functions of averages (including indicator functions), so we think that our definition of micro moments is fairly nonrestrictive. We discuss common summary statistics in Section 5.

Model analogs

Our assumptions about consumer and survey sampling allow us to compute the model analog for each observed summary statistic $f_m(\bar{v})$. Under the model, each micro moment part $\bar{v}_p(\theta)$ is defined as the expectation of v_{pijt} conditional on the aggregate data and the parameters θ:

$$v_p(\theta) \equiv \mathbb{E}_A^\theta[v_{p i_n j_n t_n}] = \frac{\sum_{t \in \mathcal{T}} \sum_{i \in \mathcal{I}_t} \sum_{j \in \mathcal{J}_t \cup \{0\}} w_{it} \cdot s_{ijt}(\theta) \cdot w_{d_p ijt} \cdot v_{pijt}}{\sum_{t \in \mathcal{T}} \sum_{i \in \mathcal{I}_t} \sum_{j \in \mathcal{J}_t \cup \{0\}} w_{it} \cdot s_{ijt}(\theta) \cdot w_{d_p ijt}}. \tag{17}$$

Notice that we aggregate over all markets t, individuals i, and products j using the same $s_{ijt}(\theta)$ from Eq. (4), and the same w_{it} we use to compute the aggregate shares s_{jt} in Eq. (5). We rely on the sampling weights $w_{d_p ijt}$ and micro values v_{pijt} to limit each part's calculation to sub-populations of individuals and to calculate conditional expectations. Likewise, by varying the model parameters θ, we are implicitly re-weighting v_{pijt} so that the objective is to choose θ such that the model average from Eq. (17) matches the survey average from Eq. (11).

The model analog of the observed micro summary statistic $f_m(\bar{v})$ is $f_m(v(\theta))$ where $v(\theta) = (v_1(\theta), \ldots, v_{P_M}(\theta))'$. At the true θ_0, iterated expectations and the continuous mapping theorem give $m = 1, \ldots, M_M$ conditions $f_m(\bar{v}) - f_m(v(\theta_0)) \xrightarrow{P} 0$.[30] Slightly abusing the definition of a statistical moment, we will call each of these conditions a "micro moment".[31]

Micro BLP estimator

We can extend the aggregate GMM estimator in Eq. (6) with M_M new micro moments and a larger weighting matrix $\hat{W} = \text{diag}(\hat{W}_A, \hat{W}_M)$.[32] This gives a minimum distance estimator:[33]

$$\hat{\theta} = \underset{\theta}{\operatorname{argmin}} \, \hat{g}(\theta)' \hat{W} \hat{g}(\theta), \quad \hat{g}(\theta) = \begin{bmatrix} \hat{g}_A(\theta) \\ \hat{g}_M(\theta) \end{bmatrix}, \quad \hat{g}_M(\theta) = \begin{bmatrix} f_1(\bar{v}) - f_1(v(\theta)) \\ \vdots \\ f_{M_M}(\bar{v}) - f_{M_M}(v(\theta)) \end{bmatrix}. \tag{18}$$

In practice, we can concentrate out the linear parameters β and only optimize over the nonlinear parameters (Π, Σ). For each guess of (Π, Σ), we need to solve the nested fixed point for all mean utilities $\hat{\delta}_{jt}(\Pi, \Sigma)$. The micro BLP estimation algorithm is given below.

---

[30] Here, convergence in probability is not conditional on the aggregate data, so these conditions are statistically compatible with the aggregate moments $\mathbb{E}[\xi_{jt} \cdot z_{jt}] = 0$.

[31] If $f_m(\bar{v}) = \bar{v}_p$ is a simple average, condition m can be interpreted without abusing terminology as a moment $\mathbb{E}[v_{pijt} - v_p(\theta_0)] = 0$. If all summary statistics were simple averages, the minimum distance estimator we will define shortly would instead be a GMM estimator.

[32] The optimal weighting matrix is block diagonal because the aggregate and micro moments are uncorrelated (see Appendix E).

[33] Again, we typically solve this problem twice, once with an initial weighting matrix and again with the optimal one, and, if appropriate, optimal instruments and optimal micro moments. With micro moments, there is no "canonical" choice for the initial weighting matrix, like the 2SLS weighting matrix for the aggregate estimator. Instead, we prefer to compute and invert all moments' covariances at some initial guess for θ_0, which could be informed by estimators based on aggregate data.

Algorithm 1 Nested Fixed Point with Micro Moments.

For each guess of the nonlinear parameters (Π, Σ):

1. For each market $t \in \mathcal{T}$, solve Eq. (5) for $\hat{\delta}_{jt}(\Pi, \Sigma)$ for all products $j \in \mathcal{J}_t$. Conlon and Gortmaker (2020) describes and evaluates different solvers in Sections 3 and 5.

2. For each micro moment $m = 1, \ldots, M_M$, compute $f_m(v(\theta)) = f_m(v(\hat{\delta}(\Pi, \Sigma), \Pi, \Sigma))$ in Eq. (17). Stack the micro sample moments $\hat{g}_M(\theta) = (f_1(\overline{v}) - f_1(v(\theta)), \ldots, f_{M_M}(\overline{v}) - f_{M_M}(v(\theta)))'$.

3. Recover linear parameters $\hat{\beta}(\Pi, \Sigma)$ from the linear IV GMM regression $\delta_{jt}(\Pi, \Sigma) = x'_{jt}\beta + \xi_{jt}$. Conlon and Gortmaker (2020) describes fixed effect absorption in Section 3 and the regression in Appendix A.

4. Compute residual unobserved qualities $\hat{\xi}_{jt}(\theta) = \hat{\delta}_{jt}(\Pi, \Sigma) - x'_{jt}\hat{\beta}(\Pi, \Sigma)$. Construct the aggregate sample moments $\hat{g}_A(\theta) = \frac{1}{N_A} \sum_{t \in \mathcal{T}} \sum_{j \in \mathcal{J}_t} \hat{\xi}_{jt}(\theta) \cdot z_{jt}$.

5. Stack sample moments into $\hat{g}(\theta) = (\hat{g}_A(\theta)', \hat{g}_M(\theta)')'$ and construct the objective $\hat{g}(\theta)' \hat{W} \hat{g}(\theta)$.

Since early uses of the micro BLP estimator in Petrin (2002) and Berry et al. (2004a), a wide range of papers, many of which we reference in Section 1, have extended the aggregate BLP estimator with various forms of moments based on micro data. Although each paper uses its own notation and language, in Section 5 we describe how most of these cases fit into the framework considered in this paper.

Although variants of the micro BLP estimator have been used extensively in practice, its econometric properties have received less attention than those of the aggregate estimator. Appendices sometimes provide heuristic discussions of asymptotic covariances (e.g., in Petrin, 2002; Berry et al., 2004a), and Grieco et al. (2023a) provide formal analysis of many markets asymptotics for their likelihood estimator. However, the only formal asymptotic analysis of a special case of the micro BLP estimator in Eq. (18) of which we are aware is in Myojo and Kanazawa (2012), which extends the many products asymptotics of Berry et al. (2004b) with micro moments of the specific form used by Petrin (2002).[34] Both of these papers also study the effect of simulation error, which, again, we omit from this article, but think may be an interesting direction for future research.

In Appendix E we derive asymptotic variances for the general micro BLP estimator under different asymptotic thought experiments: (a) many markets, including those covered by surveys; (b) many markets, few with surveys, but the surveys are large; and (c) few markets, but markets and surveys are both large. A convenient result is that the choice of thought experiment does not affect how we compute the estimator or its asymptotic variance. Additionally, consistent estimators of standard errors can be formed without any external information about the sampling error in the summary statistics $f_m(\overline{v})$ other than the number of observations N_d.[35] This means that in order to do valid inference, researchers do not need to know sample covariances or standard errors for the summary statistics they are matching.[36]

Weighted micro data

So far, there are three places where weights can show up. It is worth clarifying their different roles. First, w_{it} measures the share of *all* consumers in market t who are of type i where the type contains both observed (demographic) and unobserved heterogeneity. The choice of w_{it} should be largely unaffected by the micro data.[37] Second, w_{dijt} is the probability that a consumer in market t of type i who chooses j is selected to be in micro dataset d. Third, although the notation in Eq. (11) suggests that micro parts $\overline{v}_p$ are simple averages, many surveys datasets involve weighting schemes in order to better approximate the demographics or choices of the target population.

As an example, the simple average of income among NielsenIQ panelists tends to be higher than the national average. NielsenIQ provides *projection factors* so that after weighting, the demographics of their panelist sample is broadly demographically similar to the entire US population (including incomes). This presents a choice to the researcher: define $\overline{v}_p$ as the simple average of panelist income or as the projection factor-weighted average of panelist income (or to construct custom projection factors that are better suited to one's setting). We expect that in many cases, the latter will be preferred as researchers are often interested in estimating the preferences of an overall population.

As in many surveys, the NielsenIQ projection factors can be interpreted as *inverse sampling weights* $\widetilde{w}_{dijt} \propto 1/w_{dijt}$, which adjust for non-representative selection into the micro dataset. In this case we could multiply our "micro values" v_{pijt} by $\widetilde{w}_{dpijt}$ to produce valid estimates of quantities across *all* consumers, not just consumers selected to be in the micro dataset.

---

[34] Myojo and Kanazawa (2012) also incorporate supply-side moments and run a Monte Carlo experiment. In contrast, our focus in this article is on simply deriving asymptotic variances, but for a broader class of micro BLP estimators under a variety of different asymptotic thought experiments.

[35] The intuition is the same as for classical GMM estimation, for which the researcher does not need to have a dataset with sample covariances between moments because these covariances can be estimated after obtaining a consistent estimator for the parameters. Specifically, given N_d and sampling weights w_{dijt}, we can form a consistent estimator of the covariance $\mathbb{C}_A(v_{p i_n j_n t_n}, v_{q i_n j_n t_n})$ between each pair of micro parts p and q, and use the delta method to obtain the asymptotic covariance matrix for the micro moments. See equations (E15) and (E16) in Appendix E.

[36] By default, PyBLP computes analytic asymptotic covariances. However, it does allow researchers to specify their own asymptotic covariance matrix for micro moments, so that if researchers can use alternative measures of this matrix, if desired.

[37] In most specifications the researcher will use equally weighted pseudo-random Monte Carlo draws so that $w_{it} = \frac{1}{|I_t|}$ or quadrature rules over a (multivariate) standard normal distribution.

For concreteness, consider the running example of minivans and kids. If we assume that the survey was representative, sampling weights should depend only on market size, whether the market is in 2023, and purchasing a car: $w_{dijt} \propto \mathcal{M}_t \cdot 1\{t \in \mathcal{T}_{2023}, j \neq 0\}$. In this case, $\overline{\text{kids}}_{2023}$ from Eq. (15) represents a consistent estimate of the average number of children among households that purchased a car in 2023.

Another possibility is that the survey over-sampled high-income households (perhaps as "likely automobile buyers"), using sampling weights proportional to some known, increasing function of household income: $w_{dijt} \propto g(\text{income}_{it}) \cdot \mathcal{M}_t \cdot 1\{t \in \mathcal{T}_{2023}, j \neq 0\}$. In this case, a simple average $\overline{\text{kids}}_{2023}$ over $v_{1i_nj_nt_n} = \text{kids}_{i_nt_n}$ is inconsistent for its population counterpart. However, if the survey administrator computed inverse sampling weights $\widetilde{w}_{dijt} \propto 1/w_{dijt}$ and instead reported a weighted average with $v_{1ijt} = \widetilde{w}_{dijt} \cdot \text{kids}_{it}$, then $\overline{\text{kids}}_{2023}$ would be consistent.

When defining the model analog $f_m(v(\theta))$ of a micro statistic $f_m(\overline{v})$, it is important to know whether and how this statistic has already been weighted. If $f_m(\overline{v})$ has already been adjusted (e.g., with inverse sampling weights) so that it is a valid estimate of some quantity across *all* consumers, then we can drop the sampling probabilities w_{dijt} from the right-hand side of the model analog in Eq. (17).[38] On the other hand, if $\overline{v}_p$ is a simple average over a selected sample, we need to take the sampling probabilities w_{dijt} into account. A simple sanity check is to compare the distribution of each of the demographics under the demand model (with just the w_{it} weights), to the demographics of the corresponding micro dataset. This comparison is feasible if we condition on demographics i and markets t, but not if we condition on choices j which depend on the unknown parameters θ_0.

The formula in Eq. (17) provides some ambiguity in how we define micro sampling weights w_{dijt} and micro part values v_{pijt}, particularly for conditional expectations. Suppose we were only interested in the average number of children among minivan buyers, $\overline{\text{kids}}_{2023}^{\text{mini}}$. Previously, we represented this with $f_m(\overline{v}) = \overline{v}_3/\overline{v}_2$ where

$$w_{dijt} \propto \mathcal{M}_t \cdot 1\{t \in \mathcal{T}_{2023}, j \neq 0\}, \qquad \begin{aligned} v_{2ijt} &= 1\{j \in \mathcal{J}_{\text{mini}}\}, \\ v_{3ijt} &= \text{kids}_{it} \cdot 1\{j \in \mathcal{J}_{\text{mini}}\}. \end{aligned} \tag{19}$$

An alternative would be to instead condition the micro dataset on only minivan buyers, and use only a single micro part $f_m(\overline{v}) = \overline{v}_1$ instead of the ratio:

$$w_{dijt} \propto \mathcal{M}_t \cdot 1\{t \in \mathcal{T}_{2023}, j \in \mathcal{J}_{\text{mini}}\}, \quad v_{1ijt} = \text{kids}_{it}. \tag{20}$$

After plugging into Eq. (17) and evaluating $f_m(\overline{v})$, both of these will yield the same number: $\overline{\text{kids}}_{2023}^{\text{mini}}$. Though the two approaches contain identical information, the first approach may be preferred, even though the second may appear simpler.

The main disadvantage of the second approach is that if, as before, we also wanted to include the average number of children among all car buyers, $\overline{\text{kids}}_{2023}$, these would now be defined over two different micro datasets and would no longer have a well-defined covariance. In order to correctly calculate weighting matrices and perform inference in Appendix E, we require that each micro dataset be *statistically independent*. This is impossible if one micro dataset is simply a subset of another. This requires care in how datasets (and corresponding survey weights) are constructed in order to provide correct inference.

A different but related reason for using a weighted average micro part $\overline{v}_p$ is if one has direct information about choice probabilities s_{ijt}. For example, absent unobserved heterogeneity, a dataset may directly report the share s_{ijt} of times a consumer of type i in market t chooses j. Relatedly, carefully-designed surveys may elicit subjective choice probabilities s_{ijt} directly rather than stated choices j_n (e.g., Blass et al., 2010). In these cases, it may be appropriate to weight one's micro values v_{pijt} by the observed choice probabilities.[39] The micro sample size N_d appropriate for conducting inference will depend on assumptions about how the observed shares or subjective choice probabilities were generated.[40]

5. Standard micro moments

The empirical literature has used a variety of different micro moments. In Table 3 we list popular micro moments and the papers from Table 1 that use variants of them.

Demographic information

Many surveys report information that links purchase behavior to demographic variables. Our running example will be Petrin (2002), which uses summary statistics from a random survey of consumers to help estimate parameters in Π on interactions between consumer demographics and product characteristics.

Petrin (2002) observes the share of consumers in a certain income group $i \in \mathcal{I}_m$ who purchase a new vehicle, and uses this information to incorporate a "$\mathbb{P}(j \neq 0 \mid i \in \mathcal{I}_m)$" moment. We develop this notation-abusing shorthand to refer to a micro moment

---

[38] Using PyBLP, this amounts to setting w_{dijt} equal to some constant.

[39] If the observed micro data are $\{s_{i_nj_nt_n}\}_{n \in \mathcal{N}_d}$ and each $s_{i_nj_nt_n}$ is a consistent estimator for s_{ijt}, then $\overline{v}_p = \frac{1}{N_d} \sum_{n \in \mathcal{N}_d} s_{i_nj_nt_n} \cdot v_{pi_nj_nt_n}$ is consistent for the same model analog $v_p(\theta_0)$ in Eq. (17) as before.

[40] For shares, N_d is ideally be the number of *independent* underlying choices. If based on correlated choices of only a few individuals, a conservative N_d is the number of these individuals. For subjective choice probabilities, one may wish to follow Blass et al. (2010) and use a clustered bootstrap to compute a custom asymptotic covariance matrix for micro moments (see Footnote 36).

Table 3

Micro moment examples.

Shorthand	Papers
"$\mathbb{P}(j \in \mathcal{J}_m \mid i \in \mathcal{I}_m)$"	Petrin (2002), Thomadsen (2005), Goeree (2008), Nakamura and Zerom (2010), Beresteanu and Li (2011), Li (2012), Starc (2014), Ching et al. (2015), Li et al. (2015), Barwick et al. (2021), Li (2018), Li et al. (2018), Bodéré (2023)
"$\mathbb{E}[y_{rit} \mid j \in \mathcal{J}_m]$"	Petrin (2002), Ciliberto and Kuminoff (2010), Li (2012), Copeland (2014), Nurski and Verboven (2016), Murry (2017), Wollmann (2018), Backus et al. (2021), Armitage and Pinter (2022), Döpper et al. (2024), Durrmeyer (2022), Weber (2022), Conlon and Rao (2024)
"$\mathbb{E}[x_{cjt} \mid i \in \mathcal{I}_m, j \neq 0]$"	Starc (2014), Grieco et al. (2023b), Neilson (2021), Weber (2022), Bodéré (2023), Conlon and Rao (2024)
"$\mathbb{C}(x_{cjt}, y_{rit} \mid j \neq 0)$"	Berry et al. (2004a), Nurski and Verboven (2016), Backus et al. (2021), Durrmeyer (2022), Montag (2024), Calder-Wang and Kim (2024)
"$\mathbb{C}(x_{cjt}, x_{ek(-j)t} \mid j, k \neq 0)$"	Berry et al. (2004a), Grieco et al. (2023b), Montag (2024)

This table lists examples of micro moments that we discuss in Section 5. Each row lists our notation-abusing shorthand and empirical papers from Table 1 that have used essentially the same micro moment.

m that matches $f_m(\overline{v}) = \overline{v}_1/\overline{v}_2$ with micro values $v_{1ijt} = 1\{j \neq 0\} \cdot 1\{i \in \mathcal{I}_m\}$ and $v_{2ijt} = 1\{i \in \mathcal{I}_m\}$.[41] Intuitively, this type of micro moment should help estimate a coefficient in Π that shifts utility for consumers in the income group.

To target a coefficient in Π on the interaction between family size and a minivan dummy, Petrin (2002) could discretize family size y_{rit} into groups of consumers $i \in \mathcal{I}_m$, collect minivans into a group of products $j \in \mathcal{J}_m$ (e.g., minivans), and incorporate similar "$\mathbb{P}(j \in \mathcal{J}_m \mid i \in \mathcal{I}_m)$" moments. Often, surveys only collect information by broad demographic groups like $\mathcal{I}_m$. However, Petrin (2002) observes the mean family size of those who purchase minivans, and uses this to incorporate a "$\mathbb{E}[y_{rit} \mid j \in \mathcal{J}_m]$" moment, which intuitively contains more information than a single discretized counterpart.

Similarly, surveys that collect data about individual products rather than just broad categories of choices can be even more informative. For a product characteristic x_{cjt} such as price or size that is more granular than $1\{j \in \mathcal{J}_m\}$, matching "$\mathbb{E}[x_{cjt} \mid i \in \mathcal{I}_m, j \neq 0]$" could be more useful for estimating a coefficient in Π on the corresponding characteristic.

Even more potentially informative is the covariance "$\mathbb{C}(x_{cjt}, y_{rit} \mid j \neq 0)$" or interaction "$\mathbb{E}[x_{cjt} \cdot y_{rit} \mid j \neq 0]$" between a product characteristic x_{cjt} and a demographic y_{rit}.[42] Unlike both "$\mathbb{E}[y_{rit} \mid j \in \mathcal{J}_m]$" and "$\mathbb{E}[x_{cjt} \mid i \in \mathcal{I}_m, j \neq 0]$", which discretize x_{cjt} and y_{rit} into broad categories, a covariance potentially contains more useful information about a coefficient in Π on the interaction between x_{cjt} and y_{rit}. Although more demanding on the available micro data, there have been a few papers that have matched covariances (see Table 3).[43]

Many useful summary statistics can be written as a function of simple averages. For example, correlations and regression coefficients are covariances scaled by smooth functions of variances. PyBLP supports all such forms of micro moments, requiring only that the user specify the function $f_m(\cdot)$, as well as its derivative for computing objective gradients and delta method-based covariances.

Second choices

First incorporated in BLP-style estimation by Berry et al. (2004a), "second choices" are a particularly useful form of micro data that requires additional notation. What choices consumers would have made had their first choice been unavailable provides a great deal of information about substitution patterns, and we explain how to incorporate this information below.

Each consumer n in a micro dataset $d \in D$ with second choices has an additional characteristic k_n. Given a market $t_n = t$ and type $i_n = i$, a consumer chooses $j \in \mathcal{J}_t \cup \{0\}$ first and $k \in \mathcal{J}_t \cup \{0\} \setminus \{j\}$ second with probability $\mathbb{P}_A(j_n = j, k_n = k \mid t_n = t, i_n = i) = s_{ijkt}$. Idiosyncratic preferences ε_{ijt} remain the same across first and second choices. With ε_{ijt} distributed type I extreme value, the probability of the joint event can be written in a familiar form, $s_{ijkt} = s_{ijt} \cdot s_{ik(-j)t}$ where $s_{ik(-j)t} = s_{ikt}/(1 - s_{ijt})$ is the probability of choosing k when j is eliminated from the choice set.[44] In practice, we derive and use a less intuitive but more general expression $s_{ijkt} = s_{ik(-j)t} - s_{ikt}$, which also works for the previously-mentioned nested logit variant discussed in Appendix B.[45]

---

[41] This assumes the underlying dataset d is not selected, $w_{dijt} = 1$. If based on a survey the samples only those in the income group, $w_{dijt} = 1\{i \in \mathcal{J}_m\}$, this shorthand would refer to a micro moment that simply matches the share $f_m(\overline{v}) = \overline{v}_3$ of inside purchases with $v_{3ijt} = 1\{j \neq 0\}$.

[42] In a dataset d that already conditions on inside purchase, $w_{dijt} = 1\{j \neq 0\}$, this shorthand refers to a micro moment m that matches $f_m(\overline{v}) = \overline{v}_1 - \overline{v}_2 \cdot \overline{v}_3$ with values $v_{1ijt} = x_{cjt} \cdot y_{rit}$, $v_{2ijt} = x_{cjt}$, and $v_{3ijt} = y_{rit}$.

[43] Nurski and Verboven (2016) match actual covariances, while Berry et al. (2004a) match two moments: "$\mathbb{E}[x_{cjt} \cdot y_{rit} \mid j \neq 0]$" and "$\mathbb{E}[y_{rit} \mid j \neq 0]$". Since "$\mathbb{E}[x_{cjt} \mid j \neq 0]$" is equal to a fixed constant, these two moments span the single covariance.

[44] For more details see Conlon and Mortimer (2021) and the "individual diversion ratio". The expression $D_{j \to k,i} = s_{ik(-j)t} = s_{ikt}/(1 - s_{ijt})$ works for type I extreme value ε_{ijt}, but for other distributions such as that used by the nested logit model in Appendix B, $s_{ik(-j)}$ can be computed numerically by removing j from the choice set and computing the probability of choosing k.

[45] That is, $\mathbb{P}_\varepsilon(u_{ijt} > u_{ikt} > u_{i\ell t}, \forall \ell \neq j, k) = \mathbb{P}_\varepsilon(u_{ikt} > u_{i\ell t}, \forall \ell \neq j, k) - \mathbb{P}_\varepsilon(u_{ikt} > u_{i\ell t}, \forall \ell \neq k)$. The second term is simply s_{ikt}. The first term can be equivalently expressed as $\lim_{\delta_{jt} \to -\infty} s_{ikt}$, which equals $s_{ik(-j)t}$ for both the simple and nested logit models.

The survey sampling probability $\mathbb{P}_A(n \in \mathcal{N}_d \mid t_n = t, i_n = i, j_n = j, k_n = k) = w_{dijkt}$ can also depend on second choices. For example, $w_{dijkt} \propto \mathcal{M}_t \cdot 1\{j, k \neq 0\}$ would generate a random sample of consumers whose first and second choices were both inside alternatives.

Each micro moment part p based on a micro dataset d_p with second choices has micro values v_{pijkt} that can depend on second choices. For example, if $\bar{v}_p$ is the share of participants in a survey whose second choice was in some set $\mathcal{K}_p$ (e.g., Ford vehicles or light trucks), its micro values are $v_{pijkt} = 1\{k \in \mathcal{K}_p\}$. The conditional expectation of micro values based on second choices is

$$v_p(\theta) = \frac{\sum_{t \in \mathcal{T}} \sum_{i \in \mathcal{I}_t} \sum_{j \in \mathcal{J}_t \cup \{0\}} \sum_{k \in \mathcal{J}_t \cup \{0\} \setminus \{j\}} w_{it} \cdot s_{ijkt}(\theta) \cdot w_{d_p ijkt} \cdot v_{pijkt}}{\sum_{t \in \mathcal{T}} \sum_{i \in \mathcal{I}_t} \sum_{j \in \mathcal{J}_t \cup \{0\}} \sum_{k \in \mathcal{J}_t \cup \{0\} \setminus \{j\}} w_{it} \cdot s_{ijkt}(\theta) \cdot w_{d_p ijkt}}. \tag{21}$$

It is conceptually straightforward to incorporate third or fourth choices by adding more subscripts and sums. We limit our attention to second choices because additional sums severely increase computational cost and required notation.[46]

In papers such as Berry et al. (2004a) that use second choice data, a popular statistic is the covariance "$\mathbb{C}(x_{cjt}, x_{ek(-j)t} \mid j, k \neq 0)$" between first and second choice characteristics x_{cijt} and x_{ekt}.[47] Intuitively, this should contain information about a parameter in Σ that measures the variance of unobserved preference heterogeneity v_{cit} for x_{cijt} if $e = c$, or the covariance between unobserved preferences v_{cit} and v_{eit} for x_{cijt} and x_{eijt} if $e \neq c$. Holding mean preferences δ_{jt} equal, if when j is eliminated from the choice set consumers tend to select a second choice k that has a very similar characteristic $x_{ckt} \approx x_{cjt}$, it must be that v_{cit} has a high variance. Otherwise, we would expect to see proportionate substitution to all remaining alternatives.

Relatively complete data on consumers' first and second choices is becoming more common in empirical research. In these cases, researchers may have survey data which measures $\mathbb{P}_A(j_n = j, k_n = k \mid n \in \mathcal{N}_d)$ directly. That is, they may observe first and second choices in aggregate, but not necessarily the corresponding demographic information for the consumers. For example, Grieco et al. (2023b) have survey data from Maritz that surveys new car purchasers both on which car they purchased and what model they would purchase if their choice were unavailable. Conlon et al. (2023) use the same survey data, and show that it is possible to provide semi-parametric (mixed logit) estimates of utilities using only first and second choices from a single market. In our empirical example in Section 8, we collect simple second choice data from an online survey. In the UK, a typical survey question asked by the Competition and Markets Authority (CMA) to evaluate a potential merger is "where would you have made your purchases today if this store were closed for six months?" (Reynolds and Walters, 2008).

A common data constraint is that many surveys may not collect information about individual products or product characteristics, but only for groups of products. Conceptually, it is straightforward to incorporate information on how many consumers would substitute to another minivan or pickup truck without specifying the brand: "$\mathbb{P}(k(-b(j)) \in \mathcal{K}_m \mid j \in \mathcal{J}_m)$" with $v_{mijkt} = 1\{k \in \mathcal{K}_m\}$ and $w_{dijkt} = 1\{j \in \mathcal{J}_m\}$. These kinds of information might be especially useful if the goal is to estimate a random coefficient on a dummy for "pickup truck" or "minivan".

One extension available in PyBLP is elimination not only of the exact first choice j, but a group of products $h(j)$ containing j.[48] This extension can be useful when second choice data is at a higher level of aggregation than products. For example, the researcher may have access to information about how consumers substitute when their favorite brand $h(j) = b(j)$ is eliminated from the market (e.g., Coca Cola), which includes their first choice product j (e.g., a 2-liter bottle of Coca Cola). Alternatively, we might observe how consumers substitute when all hospitals from the Partners system were eliminated from the choice set.

Compatibility issues

Another challenge with combining aggregate and micro data is compatibility. Variables may be measured or defined slightly differently, data may be collected at different frequencies or during different periods, and survey data may oversample individuals in unexpected ways.

A frequent source of incompatibilities arises when the distribution of characteristics x_{jt}, demographics y_{it}, or choices s_{jt} differs significantly between the aggregate purchase data and the micro survey data. This could arise because the income of shoppers in a survey differs from the income of shoppers at a particular store, or if surveyed consumers face a different set of products (or characteristics such as prices) than those in the aggregate data. It could also arise because of bad luck or poor survey design. For example, nationally, Coca-Cola has around a 48% market share, while Pepsi has around a 20% market share. If we surveyed individuals about their soft drink preferences (as we do in Section 8) and found that more consumers preferred Pepsi to Coca-Cola, this would present a potential incompatibility with the aggregate sales data.

One likely violation of compatibility that is likely to arise in practice is that many papers match micro moments averaged over the entire sample, rather than a subset of markets. An example of correctly addressing compatibility can be found in Grieco et al. (2023b) where the authors observe aggregate purchase data from 1980 to 2018, as well as individual survey data from the years 1991, 1999, 2005, 2015. Because the distribution of prices and characteristics are quite different in 1991 and 2015, it is important to condition on the year when constructing micro datasets so that $w_{1991,ijt} = \mathcal{M}_t \cdot \{j \neq 0, t \in \mathcal{T}_{1991}\}$ and $w_{2015,ijt} = \mathcal{M}_t \cdot \{j \neq 0, t \in \mathcal{T}_{2015}\}$,

---

[46] With longer lists of ranked choice data, researchers often consider full maximum likelihood type approaches rather than aggregated moments (see, e.g., Agarwal and Somaini, 2020).

[47] In practice, Berry et al. (2004a) split this covariance up and match two moments, "$\mathbb{E}[x_{cjt} \cdot x_{ek(-j)t} \mid j, k \neq 0]$" and "$\mathbb{E}[x_{ek(-j)t} \mid j, k \neq 0]$", to work with simple averages.

[48] The only real difference is that we compute $s_{ik(-h(j))t}$ instead of $s_{ik(-j)t}$. With ε_{ijt} distributed type I extreme value, we can write $s_{ik(-h(j))t} = s_{ikt}/(1 - \sum_{h(\ell) = h(j)} s_{i\ell t})$.

rather than averaging over all years.

As another example, Backus et al. (2021) compute both the chain-year specific joint distribution of characteristics (income and presence of children) when forming w_{it} and calculate separate micro moments for each chain-year. This results in a very large number of micro moments, but guarantees compatibility in the sense that this correctly matches individual shoppers to the correct product assortment and prices. By conditioning on chain, this avoids the possibility that the NielsenIQ panelists systematically shop at a different set of supermarket chains than predicted by the aggregate sales patterns $\mathcal{M}_t$. This issue will arise frequently with the NielsenIQ data, where not all supermarket chains report scanner data sales, but panelists report purchases at all stores whether or not they are in the scanner dataset.

Another example of where compatibility of micro data presents a challenge can be found in Conlon and Rao (2024). A well-known problem with survey data on alcohol consumption is that reported per capita consumption reflects only 30%–40% of alcohol purchases. While it might be tempting to construct moments to match the probability of purchasing a unit of alcohol conditional on income within some range, "$\mathbb{P}(j \neq 0 \mid y_{it} \in [\underline{y}_q, \overline{y}_a])$", these moments are incompatible with aggregate sales data. That is, there is no set of parameters θ such that one could match both the aggregate no purchase share s_{0t} and the purchase or no-purchase shares by income. One approach would be to not include micro moments from an incompatible survey, but the other is to define compatible moments that are potentially less efficient. The authors apply Bayes Rule and match the probability that a given unit of alcohol is purchased by households of each income level, "$\mathbb{P}(y_{it} \in [\underline{y}_q, \overline{y}_a] \mid j \neq 0)$". This avoids the issue that the marginal distribution of purchasing alcohol "$\mathbb{P}(j \neq 0)$" is completely different across the aggregate and micro datasets, while still including information on the relationship between alcohol purchases and income.[49]

In general, researchers may wish to match summary statistics that are compatible with their full dataset, rather than use all the information in a dataset that they suspect is less compatible. In our Monte Carlo experiments in Section 7, we provide a typical example where income is measured differently across datasets, but being careful about what information to match can still deliver a consistent estimator.

In other settings, researchers may be unsure about whether there are compatibility issues. The good news is that testing for compatibility is straightforward (Imbens and Lancaster, 1994). If there is sufficient variation from the aggregate data (or from micro datasets that are known to be compatible) to identify the model, we can use an overidentification test. Our preferred approach is to estimate the model without the potentially incompatible micro moments to obtain $\hat{\theta}$, and then form a test statistic from differences $\hat{\Delta}_M = f(\overline{v}) - f(v(\hat{\theta}))$ between observed and estimated micro statistics,[50]

$$\text{Wald} = N_A \hat{\Delta}'_M \hat{S}_M^{-1} \hat{\Delta}_M \rightsquigarrow \chi^2(M_M) \tag{22}$$

where $\hat{S}_M^{-1}$ is the properly-scaled asymptotic covariance matrix of the micro moments that we derive in Appendix E, and which is automatically reported by PyBLP for standard error calculations.

6. Optimal micro moments

Having discussed common forms of micro moments, we discuss optimality. How should we choose what statistics to match, given data availability, computational resources, compatibility, and interpretability requirements?

Matching scores

In terms of data availability, a best-case scenario is observing not just a few micro statistics $\overline{v}_m$, but rather a complete dataset of all sampled consumers' markets, choices, and demographics $\{(t_n, j_n, y_{i_n t_n})\}_{n \in \mathcal{N}_d}$. When we say "complete" we must observe not only individual choices, but also all of the relevant demographics required to compute the choice probabilities in Eq. (4). Rather than use the standard micro moments from Section 5, we can use the scores from the individual data likelihood and combine them with the aggregate moments from aggregate estimator in Eq. (6). This has the advantage that it will efficiently use all of the information in the micro dataset, and also that it may reduce the overall number of micro moments used in estimation. The disadvantage is that the individual scores are infeasible (in that they depend on the unknown θ_0) and require an initial estimate $\hat{\theta}$ in order to compute them.

Our preferred approach is a two-step procedure that minimizes computational costs while still making full use of the micro data.[51] After obtaining a first-stage estimator $\hat{\theta}$ with sub-optimal micro moments, the researcher constructs optimal micro moments m that match the average score function $f_m(\overline{v}) = \overline{v}_m$ for each micro dataset d_m evaluated at each nonlinear parameter θ_m:[52]

$$v_{mijt}(\hat{\theta}) = \frac{\partial \log \mathbb{P}_A^{\hat{\theta}}(t_n = t, j_n = j, y_{i_n t_n} = y_{it} \mid n \in \mathcal{N}_{d_m})}{\partial \theta_m}. \tag{23}$$

We use the notation $\mathbb{P}_A^{\hat{\theta}}$ to define a probability that is conditional on all the aggregate data, including estimated unobserved qualities $\hat{\xi}_{jt}$. In words, the score tells us how the log (conditional) choice probability varies with parameters θ for an individual

---

[49] This relies on the assumption that higher or lower income individuals are not systematically under-reporting relative to other income groups.

[50] If there are some compatible micro moments, these can be used to obtain $\hat{\theta}$, should have their elements in $\hat{\Delta}_M$ set to zero, and their count should be subtracted from the χ^2 degrees of freedom.

[51] This approach is closely related to the "one-step" method discussed, for example, in Section 3.4 of Newey and McFadden (1994).

[52] This can be done in PyBLP with only a few lines of code. See Figure G1 in Appendix G.

with demographics y_{it} in market t. Conveniently, we only need to calculate this for the option j that an individual chooses.

In Appendix G we provide full expressions for micro data scores and demonstrate how to compute them with PyBLP. Incorporating second choices into this procedure requires adding additional subscripts and having a more complicated score expression, so here we focus on first choices.

First, we compute the score $v_{mi_nj_nt_n}(\hat{\theta})$ in Eq. (23) evaluated at each observation $n \in \mathcal{N}_d$ and take their average over individuals, choices, and markets to get $\bar{v}_m(\hat{\theta})$. This becomes the target that the optimal micro moments aim to match. We also pre-compute $v_{mijt}(\hat{\theta})$ for each possible (i, j, t) so that scores only need to be computed a single time. For each guess of θ, we only need compute choice probabilities $s_{ijt}(\theta)$, just like for standard micro moments. After also constructing an estimator of the optimal weighting matrix and, if desired, an approximation to Chamberlain's (1987) optimal instruments, the researcher obtains the second-stage estimator.

Algorithm 2 Optimal Micro BLP Estimator.

Given a sense for reasonable bounds for the nonlinear parameters (Π, Σ), for example from running a version of the IV regression in Eq. (8) and Appendix C:

1. Use sub-optimal micro moments to obtain a first-stage estimator $\hat{\theta}$ by minimizing the objective constructed by Algorithm 1. We recommend drawing a few different starting values from within reasonable parameter bounds. In Conlon and Gortmaker (2020) we describe and evaluate other recommended practices for nonlinear optimization in Sections 3 and 5.

2. Approximate Chamberlain's (1987) optimal instruments $\hat{z}_{jt}(\hat{\theta})$ by following Algorithm 2 in Conlon and Gortmaker (2020), originally proposed by Berry et al. (1999).

3. Approximate the target micro moment m for each dataset d_m and nonlinear parameter p_m pair by computing $\bar{v}_m(\hat{\theta}) = \frac{1}{N_{d_m}} \sum_{n \in \mathcal{N}_{d_m}} v_{mi_nj_nt_n}(\hat{\theta})$ in Eq. (23).

4. Estimate the optimal weighting matrix $\hat{W}(\hat{\theta})$ by inverting an estimator of the asymptotic covariance matrix of the moments in Appendix E.

5. Use approximations to the optimal IVs, micro moments, and weighting matrix to obtain the second-stage estimator by minimizing the objective constructed by Algorithm 1. Again, we recommend drawing a few different starting values from within reasonable parameter bounds.

In Appendix F we show that if the first-stage estimator is consistent, then the second-stage estimator is asymptotically efficient within the class of all possible micro BLP estimators. By this, we mean that Algorithm 2 delivers an estimator with an asymptotic variance that is no greater than that of another micro BLP estimator based on any weighting matrix $\hat{W}$, instruments z_{jt}, micro moment functions $f_m(\cdot)$, and micro values v_{pijt}. Restricting ourselves to this class of micro BLP estimators rules out efficiency gains from estimators outside this class, such as those that do not require that observed market shares S_{jt} exactly equal their model counterparts.[53]

Only needing to compute scores once makes the two-step approach computationally attractive. The more familiar approach of stacking scores with the original moments (e.g., in Imbens and Lancaster, 1994) would require re-computing all observations' scores for each optimization iteration over θ.[54]

Grieco et al. (2023a) point to a potential identification issue with using scores instead of the likelihood itself: population scores may have multiple zeros even when the population likelihood has a unique global maximum. In our case, an analogous issue could arise if there are multiple values of θ that satisfy the "optimal" population micro moments, and there are no overidentifying aggregate moments to help select between these multiple values of θ. Although we are unaware of any empirical examples where this has been shown to be an issue for the micro BLP approach, if this is a concern, we recommend adding overidentifying aggregate moments.[55]

A final concern is with inconsistent first-stage estimates. In practice, we recommend using standard micro moments discussed in the last section, which should typically provide consistent and credible parameter estimates for the first stage. If standard micro moments in conjunction with aggregate variation seem to only weakly identify or not identify some parameters, another option is to also match scores in the first stage, but evaluated at an informed guess of the true θ_0 rather than a consistent estimator, which in some cases may be more informative about θ than standard micro moments.[56] A final option is to not use micro BLP and instead use one of the likelihood-based approaches discussed in Section 1, which maximize the micro likelihood directly.

Intuition from scores

Often, instead of having the full results from a survey, researchers will only have access to or be willing to use summary statistics because of cost, interpretability, compatibility, confidentiality, or other data limitations. For estimating a given model, the most efficient summary statistic would be the score of the individual likelihood, averaged across all surveyed individuals. Although survey administrators are unlikely to collect scores for different models, inspecting the functional form of scores for some simple models does motivate the functional form of some of the common micro moments discussed in Section 5.

---

[53] For example, the estimator proposed by Grieco et al. (2023a) obtains efficiency gains by relaxing the share constraint, particularly when the number of micro observations is a nontrivial proportion of the observations underlying aggregate market shares.

[54] Technically, one only need compute scores for each distinct set of demographic values, product choice, and market. This speeds up computation when demographics take on only a few discrete values and purchases are not spread across many products.

[55] If aggregate variation is limited and, in sample, there are multiple *global* optima that each set the micro scores to approximately zero (and give approximately the same aggregate moments), a practical if somewhat heuristic solution is to compute the micro likelihood at each and select the one with the highest likelihood.

[56] For example, limited cross-market choice set variation and standard micro moments that do not use second choices may result in a poorly-identified Σ. Using more information in the full micro dataset may help provide a consistent first-stage estimator.

We present full score expressions in Appendix G but here consider the simplest case with $C = 1$ observed characteristic, $R = 1$ demographic, three parameters $\theta = (\beta, \pi, \sigma)$, and a micro dataset d with no selection, $w_{dijt} = 1$. First consider the case without any unobserved heterogeneity, $\sigma = 0$. The score for β is zero,[57] and for π is

$$\frac{\partial \log \mathbb{P}_A(t_n = t, j_n = j, y_{i_n t_n} = y_{it} \mid n \in \mathcal{N}_d)}{\partial \pi} = \frac{\partial u_{ijt}}{\partial \pi} - \sum_{k \in \mathcal{J}_t} s_{ikt} \cdot \frac{\partial u_{ikt}}{\partial \pi}. \tag{24}$$

in which the derivative of indirect utility for $j \neq 0$ in Eq. (1) with respect to π is

$$\frac{\partial u_{ijt}}{\partial \pi} = \frac{\partial \mu_{ijt}}{\partial \pi} + \frac{\partial \delta_{jt}}{\partial \pi} = x_{jt} \cdot y_{it} + \frac{\partial \delta_{jt}}{\partial \pi}. \tag{25}$$

Since s_{ijt} and $\frac{\partial \delta_{jt}}{\partial \pi}$ are functions of π,[58] the only term directly observed in the micro data is $x_{jt} \cdot y_{it}$. This suggests that the "$\mathbb{C}(x_{jt}, y_{it} \mid j \neq 0)$" or "$\mathbb{E}[x_{jt} \cdot y_{it} \mid j \neq 0]$" moments discussed above should be informative about π because they are similar to the score.[59] If $x_{jt} = 1$, then the primary term is simply y_{it}, suggesting that "$\mathbb{E}[y_{it} \mid j \neq 0]$" should be informative about π in this simpler case. In Section 7 we confirm this intuition with Monte Carlo experiments.

Often, demographics will be discrete (e.g., levels of education, presence of children, or binned income). For example, Petrin (2002) matches "$\mathbb{E}[x_{jt} \mid y_{it} = 1] = \mathbb{P}(j \neq 0 \mid y_{it} = 1)$" where $x_{jt} = 1$ is an indicator for all inside goods and y_{it} is an indicator for high income consumers. Intuition about informativeness is similar in this case. Up to a denominator "$\mathbb{P}(y_{it} = 1)$", which is a constant scaling factor that only depends on demographic data, matching this moment is identical to matching a "$\mathbb{E}[x_{jt} \cdot y_{it}]$" moment, which is very similar to the score.

However, matching only a single covariance or expectation leaves some information on the table because it does not span the subsequent terms in the score. Similarly, for the case with $\sigma \neq 0$, the score for π becomes an integral over unobserved heterogeneity, further distancing a single "$\mathbb{C}(x_{jt}, y_{it} \mid j \neq 0)$" moment from the true score.

To focus on the value of second choices, next consider the case with observed heterogeneity, $\sigma \neq 0$, but without any observed demographics, $\pi = 0$. The score for σ is

$$\frac{\partial \log \mathbb{P}_A(t_n = t, j_n = j, k_n = k \mid n \in \mathcal{N}_d)}{\partial \sigma} = \sum_{i \in \mathcal{I}_t} \frac{w_{it} \cdot s_{ijkt}}{\sum_{i \in \mathcal{I}_t} w_{it} \cdot s_{ijkt}} \left[\frac{\partial u_{ijt}}{\partial \sigma} + \frac{\partial u_{ikt}}{\partial \sigma} - \sum_{\ell \in \mathcal{J}_t} s_{i\ell t} \cdot \frac{\partial u_{i\ell t}}{\partial \sigma} - \sum_{\ell \in \mathcal{J}_t \setminus \{j\}} s_{i\ell(-j)t} \cdot \frac{\partial u_{i\ell t}}{\partial \sigma} \right], \tag{26}$$

in which the derivative of indirect utilities for $j, k \neq 0$ with respect to σ is

$$\frac{\partial u_{ijt}}{\partial \sigma} + \frac{\partial u_{ikt}}{\partial \sigma} = v_{it} \cdot (x_{jt} + x_{kt}) + \frac{\partial \delta_{jt}}{\partial \sigma} + \frac{\partial \delta_{kt}}{\partial \sigma}. \tag{27}$$

The only term directly observed in the micro data is $(x_{jt} + x_{kt})$. This is scaled by the average unobserved preference v_{it} among those who choose j first and k second, but the sum itself is similar to the "$\mathbb{C}(x_{jt}, x_{k(-j)t}, \mid j, k \neq 0)$" moment discussed above, suggesting that such a second choice covariance should indeed be informative about σ. And if available, the average or sum "$\mathbb{E}[x_{jt} + x_{k(-j)t} \mid j, k \neq 0]$" of first- and second-choice characteristics could be informative as well. We confirm this intuition in Section 7. Although these moments can work well in practice, only matching a covariance or sum will not fully match the expression in Eq. (26), which involves even more terms after adding in observed demographics (see Appendix G).

Inspecting scores in this way can provide some intuition for which micro moments may be informative and which may not. We provide additional examples for extensions with lognormal random coefficients and nesting parameters in Appendices A and B. In general, however, the ideal summary statistics to match will depend on the model specification and the true parameter values.

In Appendix H we provide a more systematic approach for determining which summary statistics are more or less informative about the parameters in the model, in the sense that some will be more or less correlated with the score. Given a first-stage estimator $\hat{\theta}$ and a sampling scheme w_{dijt}, we recommend simulating a micro dataset and regressing simulated scores on candidate micro values v_{pijt},[60] keeping only those sets of micro values that maximize the R^2 of the regression. In the presence of a large number of summary statistics, we also consider a LASSO-based approach. This type of heuristic selection procedure does not come with any theoretical guarantees, but it can help to identify a small number of maximally informative summary statistics that are more likely to be collected by survey administrators than model-specific average scores.

7. Monte Carlo experiments

We provide several Monte Carlo experiments to illustrate the performance of the micro BLP estimator with different micro moments. We also use our simulations to illustrate the importance of practical choices that need to be made when doing empirical research, which we further discuss in the empirical example of Section 8.

---

[57] Micro data are uninformative about β because it enters into choice probabilities s_{ijt} only through mean utilities δ_{jt}, which are pinned down by the aggregate data share constraint in Eq. (7).

[58] Since mean utilities are pinned down by the share constraint in Eq. (7), their derivatives are given by invoking the implicit function theorem: $\frac{\partial \delta_t}{\partial \pi} = \left(\frac{\partial s_t}{\partial \delta_t}\right)^{-1} \frac{\partial s_t}{\partial \pi}$.

[59] Grieco et al. (2023a) also note the similarity of "$\mathbb{C}(x_{jt}, y_{it} \mid j \neq 0)$" moments to the score for π. Their expression does not involve $\frac{\partial \delta_{jt}}{\partial \pi}$ because their estimator treats each δ_{jt} as a separate parameter rather than as an implicit function of π.

[60] In Appendix H we also demonstrate how this can be done in only a few lines of code with PyBLP.

Monte Carlo configuration

Our simulation configurations build on those of Conlon and Gortmaker (2020), which are loosely based on those of Armstrong (2016). We first describe a baseline configuration, and in the following subsections describe how we modify this configuration to compare different aspects of the micro BLP estimator.

For each configuration, we construct and estimate the model on 1,000 different synthetic datasets. In each of $T = |\mathcal{T}| = 40$ markets we randomly choose either 2, 5, or 10 firms, and have each firm produce 3, 5, or 5 products in that market. The number of products is generally between $10 < |\mathcal{J}_t| < 30$. Across markets, the number of aggregate observations is generally between $400 < N_A < 1{,}200$.

There are $C = 3$ observed product characteristics $x_{jt} = (1, x_{2jt}, p_{jt})'$: a constant, an exogenous characteristic $x_{2jt} \sim U(2, 4)$, and endogenous prices p_{jt}. We generate a realistic correlation between p_{jt} and unobserved quality ξ_{jt} by drawing ξ_{jt} and cost shocks from a mean-zero bivariate normal distribution, by drawing a cost shifter, and by numerically solving for Bertrand-Nash equilibrium prices p_{jt} and shares s_{jt} with the fixed point approach of Morrow and Skerlos (2011).[61] Since our focus is not on weak cost shifters, our marginal cost parameterization generates a strong correlation between the cost shifter and price. Instruments z_{jt} are $(1, x_{2jt})'$, the cost shifter, and the differentiation IVs of Gandhi and Houde (2020) discussed in Section 3.[62] We parameterize mean utility in Eq. (2) to give "realistic" outside shares generally between $0.6 < S_{0t} < 0.9$:

$$\delta_{jt} = \beta_1 + \beta_x x_{2jt} + \alpha p_{jt} + \xi_{jt}, \quad \beta_0 = (\beta_{01}, \beta_{0x}, \alpha_0)' = (-6, 3, -3)'. \tag{28}$$

In each market t, we generate different Monte Carlo draws to represent $|\mathcal{I}_t| = 1{,}000$ consumer types, each with an equal share $w_{it} = 1/|\mathcal{I}_t|$. For our simulations we found 1,000 types to strike a good balance between variance and compute time.[63] We do not want to create the impression that 1,000 or any other specific number of draws will be adequate for a specific setting. For empirical work, we recommend increasing the number of draws until one's estimates stabilize, and following other recommendations in Section 5 of Conlon and Gortmaker (2020) to directly check that the chosen integration rule performs well compared to other feasible alternatives.

Since income is the most common demographic to appear in demand systems, we randomly assign each market to a US state and draw $R = 1$ demographic y_{it} from a lognormal distribution fit to the 2019 American Community Survey (ACS) income distribution for that state. To start, we do not include unobserved heterogeneity when parameterizing heterogeneous utility in Eq. (3):

$$\mu_{ijt} = \pi_1 y_{it} + \pi_x x_{2jt} y_{it}, \quad \Pi_0 = (\pi_{01}, \pi_{0x}, 0)' = (-0.1, 0.1, 0)', \quad \Sigma_0 = 0. \tag{29}$$

Finally, we simulate a micro dataset d with an average of 1,000 observations per market. Since the most common type of consumer survey samples only those who select an inside alternative, we use selection probabilities $w_{dijt} = 1\{j \neq 0\}$.

To obtain an estimator $\hat{\theta} = (\hat{\beta}_1, \hat{\beta}_x, \hat{\alpha}, \hat{\pi}_1, \hat{\pi}_x)$ we follow the recipe in Algorithm 2 for the optimal micro BLP estimator, but to start we do not approximate the optimal micro moments. To solve the fixed point for $\hat{\delta}_{jt}(\Pi, \Sigma)$ and optimize over θ, we use recommended practices described in Conlon and Gortmaker (2020).[64] To numerically integrate over the distribution of income y_{it}, we resample from its true distribution.

Monte Carlo results

When reporting results from our simulations, we focus on the median absolute error (MAE) and median bias of the parameter estimators. In Appendices I and J we provide additional results measuring the performance of standard error counterfactual calculations, which are generally in line with the performance of parameter estimators across configurations. Computation was done on the Harvard Business School compute cluster.[65]

Demographic variation

In Table 4 we vary the amount of cross-market demographic variation and measure the performance of the aggregate BLP estimator. When in each market income y_{it} is drawn from a lognormal distribution fit to the same national distribution of income, there is no cross-market variation, so as discussed in Section 3, π_1 and π_x are not identified.

---

[61] Firms choose prices to maximize their products' profits $s_{jt}(p_t) \cdot (p_{jt} - c_{jt})$ subject to marginal costs $c_{jt} = 2 + 0.1 \times x_{2jt} + 1.0 \times w_{jt} + \omega_{jt}$. The cost shifter is distributed $w_{jt} \sim U(0, 1)$. Unobserved quality ξ_{jt} and the cost shock ω_{jt} are mean-zero bivariate normal with common variance 0.2 and covariance 0.1. With multi-product firms and random coefficients we cannot guarantee a unique equilibrium. Instead, we compute *an* equilibrium, which is sufficient to generate somewhat realistic variation in prices.

[62] As noted in Footnote 24, we use the "quadratic" version of differentiation IVs: $\hat{a}_{2jt} = \sum_k (x_{2jt} - x_{2kt})^2$ both alone (when we include unobserved heterogeneity) and interacted with the mean $m_t^y = \sum_i w_{it} \cdot y_{it}$ of a consumer demographic y_{it}, discussed shortly.

[63] For example, we experimented with doubling the draws for our first few tables. This doubled the compute cost but only slightly reduced the variance of our estimates, leaving the simulations' takeaways unchanged.

[64] We accelerate the fixed point with the SQUAREM method of Varadhan and Roland (2008) and use an L^∞ tolerance of 1E−14. To optimize, we supply objectives and analytic gradients to SciPy's trust region algorithm "trust-constr" and use an L^∞ gradient-based tolerance of 1E−5. For each GMM step, we draw three sets of starting values from 100% above and below the true parameter values.

[65] For our configurations, six rounds of optimization (three sets of starting values for each GMM step) typically take 1–3 minutes, plus another 30 seconds for computing optimal micro moments. Using second choice moments typically takes 3–8 times longer.

Table 4

Demographic variation.

Variation	Distributions	Markets	MAE (%)					Bias (%)				
			$\hat{\pi}_1$	$\hat{\pi}_x$	$\hat{\beta}_1$	$\hat{\beta}_x$	$\hat{\alpha}$	$\hat{\pi}_1$	$\hat{\pi}_x$	$\hat{\beta}_1$	$\hat{\beta}_x$	$\hat{\alpha}$
National	1	40	436.6	133.3	8.3	5.1	1.2	−110.3	−45.6	1.8	2.1	0.1
States	50	40	197.8	60.6	3.9	2.4	1.2	−31.3	−12.6	0.6	0.4	0.1
PUMAs	982	40	97.5	30.0	2.7	1.4	1.2	−5.8	−4.7	0.2	0.2	0.1
National	1	80	327.7	102.8	6.1	4.0	0.9	−98.5	−48.4	2.0	2.1	0.0
States	50	80	139.5	42.7	2.7	1.6	0.9	−7.4	−6.1	0.2	0.2	−0.0
PUMAs	982	80	65.9	21.3	1.9	1.0	0.8	−4.9	−2.4	0.2	0.2	−0.0

This table reports median absolute error (MAE) and median bias of parameter estimates over 1,000 simulated datasets for different amounts of cross-market demographic variation. We randomly assign each market either to the same national distribution of income, to one of 50 US states, or to one of the 982 Public Use Microdata Areas (PUMAs) used by the American Community Survey (ACS). In the last three rows, we simulate 40 more markets, keeping the same demographic distributions as in the first 40, but with different choice sets.

Table 5

Standard micro moments.

Micro moments shorthand	MAE (%)		Bias (%)	
	$\hat{\pi}_1$	$\hat{\pi}_x$	$\hat{\pi}_1$	$\hat{\pi}_x$
No Micro Moments	197.8	60.6	−31.3	−12.6
"$\mathbb{E}[y_{it} \mid j \neq 0]$"	164.8	44.9	2.9	1.4
"$\mathbb{C}(x_{2jt}, y_{it} \mid j \neq 0)$"	53.8	11.7	17.5	2.3
"$\mathbb{E}[y_{it} \mid j \neq 0]$, $\mathbb{C}(x_{2jt}, y_{it} \mid j \neq 0)$"	34.0	10.8	4.1	1.1
"$\mathbb{E}[y_{it} \mid j \neq 0]$, $\mathbb{E}[x_{2jt} \cdot y_{it} \mid j \neq 0]$"	37.6	12.0	3.2	0.7
"$\mathbb{E}[y_{it} \mid j \neq 0]$, $\mathbb{E}[x_{2jt} \mid y_{it} < \bar{y}_t, j \neq 0]$"	62.7	17.3	0.9	1.0
"$\mathbb{E}[y_{it} \mid j \neq 0]$, $\mathbb{E}[x_{2jt} \mid y_{it} < \bar{y}_t, j \neq 0]$, $\mathbb{C}(x_{2jt}, y_{it} \mid j \neq 0)$"	34.2	10.7	4.3	1.1

This table reports median absolute error (MAE) and median bias of parameter estimates over 1,000 simulated datasets for different combinations of standard micro moments. The cutoff $\bar{y}_t$ is the median income y_{it} in market t.

In the second row, randomly assigning each market to one of the 50 US states provides some cross-market variation, which gives an estimator with very little finite sample bias. However, income distributions do not vary much across states, so the estimator still has high variance, even when using the feasible approximation to the optimal instruments.[66] Assigning markets instead to the 982 Public Use Microdata Areas (PUMAs) increases the amount of cross-market income variation, further reducing the bias and variance of $\hat{\pi}_1$ and $\hat{\pi}_x$.

In the last three rows, we double the number of markets to $T = 80$ but keep the amount of cross-market demographic variation the same by re-using the demographic distribution in each $t \leq 40$ for market $t+40$. As the amount of cross-market choice set variation increases, bias and variance of $\hat{\pi}_1$ and $\hat{\pi}_x$ decrease. In line with the linear regression intuition from Section 3, more variation in demand helps estimate Π, which is identified by how cross-market demographic variation shifts demand. However, without a great deal of demographic variation, the estimator is still fairly noisy.

Since we made the cost shifter a strong instrument and did not model preference heterogeneity for price (see Appendix A for simulation results for when we do), the coefficient on price $\hat{\alpha}$ has very little bias and variance across all configurations. The performance of the linear parameter estimators $\hat{\beta}_1$ and $\hat{\beta}_x$ track the performance of the nonlinear estimators $\hat{\pi}_1$ and $\hat{\pi}_x$, so for simplicity's sake, we focus only on estimators of nonlinear parameters in subsequent results.

Standard micro moments

Sticking with $T = 40$ markets and state-level income variation, in Table 5 we illustrate the impact of standard micro moments discussed in Section 5. Matching only the mean income of those who do not choose the outside alternative with a "$\mathbb{E}[y_{it} \mid j \neq 0]$" moment somewhat reduces variance, but not by much. A "$\mathbb{C}(x_{2jt}, y_{it} \mid j \neq 0)$" moment contains more information and reduces variance a bit more, particularly for the π_x parameter whose score it approximates. However, it is only with the combination of both moments that we greatly reduce the variance of both estimators.

Since "$\mathbb{C}(x_{2jt}, y_{it} \mid j \neq 0)$" equals "$\mathbb{E}[x_{2jt} \cdot y_{it} \mid j \neq 0] + \mathbb{E}[x_{2jt} \mid j \neq 0] \cdot \mathbb{E}[y_{it} \mid j \neq 0]$", when paired with a "$\mathbb{E}[y_{it} \mid j \neq 0]$" moment it contains essentially the same information as matching the first term in the score for π_x, the interaction "$\mathbb{E}[x_{2jt} \cdot y_{it} \mid j \neq 0]$". Accordingly, both perform almost identically. However, matching a covariance could be more appealing in some settings because it is more interpretable and is more likely to be reported by a survey than, for example, the mean of an interaction term.

---

[66] Optimal instruments are well-known to reduce the bias and variance of the aggregate BLP estimator (Reynaert and Verboven, 2014; Conlon and Gortmaker, 2020).
Fig. 1. Standard Micro moment correlations.
This figure reports median absolute correlations between different micro statistics over 1,000 simulated micro datasets underlying the micro moments in Table 5. For each micro observation n in market $t_n = t$ of type $i_n = i$ with choice $j_n = j$, we compute three statistics: $x_{2jt} \cdot y_{it}$ captures variation in "$\mathbb{E}[x_{2jt} \cdot y_{it} \mid j \neq 0]$" and "$\mathbb{C}(x_{2jt}, y_{it} \mid j \neq 0)$" moments, $x_{2jt} \cdot 1\{y_{it} < \overline{y}_t\}$ captures variation in "$\mathbb{E}[x_{2jt} \mid y_{it} < \overline{y}_t, j \neq 0]$" moments, and $\partial \log \mathbb{P}_A(t, j, y_{it} \mid n \in \mathcal{N}_d)/\partial \pi_x$ is the score for π_x at the true θ_0.

A survey that does not report covariances may still report average characteristics by demographic groups, allowing us to use a "$\mathbb{E}[x_{2jt} \mid y_{it} < \overline{y}_t, j \neq 0]$" moment that matches the mean x_{2jt} for low-income consumers. Discretizing y_{it} discards some information, reducing correlation with the score for π_x, so the estimator has a higher variance. Since in this simple simulation the score for π_x is dominated by $x_{2jt} \cdot y_{it}$, adding the discretized moment on top of the continuous one does not particularly improve the performance of the estimator.[67]

To visualize the relationship between "$\mathbb{E}[x_{2jt} \cdot y_{it} \mid j \neq 0]$", "$\mathbb{E}[x_{2jt} \mid y_{it} < \overline{y}_t, j \neq 0]$", and the score, for each observation in the micro data underlying Table 5 we compute $x_{2jt} \cdot y_{it}$, $x_{2jt} \cdot 1\{y_{it} < \overline{y}_t\}$, and the score for π_x. We report their correlation matrix in Fig. 1.[68] As expected, $x_{2jt} \cdot y_{it}$ and the score have strong correlation of 0.675.[69] Discretizing y_{it} reduces the correlation with the score by around 11% to 0.6.

This same approach can be used as a diagnostic: researchers can use the score contributions of simulated individuals under the model at the estimated parameters $\hat{\theta}$, and compare these to their micro statistics (see Appendix H). While this requires an estimate of $\hat{\theta}$, it provides a simple way to measure whether the micro statistics do a good job capturing the potential micro-level variation.

When using multiple moments to target the same parameter, a natural and important question is which moments contribute the most. Honore et al. (2020), building on the sensitivity measures proposed by Andrews et al. (2017), provide a suite of diagnostics

---

[67] In more complicated simulations, for example with unobserved heterogeneity, adding additional moments can help explain variation in the more complicated score.

[68] The score is evaluated at the true θ_0. We report the absolute value of correlations, taking a median across the 1,000 simulated micro datasets.

[69] How to interpret this number? With a single parameter and a single linear micro moment, the asymptotic standard deviation (SD) of the efficient GMM estimator is one over this correlation times the score's SD (see Appendix H). Since the Normal distribution's MAD is proportional to its SD, this correlation should hence equal the ratio of MAEs obtained under the optimal moment versus the sub-optimal moment. Even though we are not in the scalar case, we see approximately this result in Table 6.

Table 6

Optimal micro moments and compatibility.

Micro moments (plus $\mathbb{E}[y_{it} \mid j \neq 0]$)	Incompatible	Optimal	MAE (%)		Bias (%)	
			$\hat{\pi}_1$	$\hat{\pi}_x$	$\hat{\pi}_1$	$\hat{\pi}_x$
"$\mathbb{C}(x_{2jt}, y_{it} \mid j \neq 0)$"			34.0	10.8	4.1	1.1
"$\mathbb{C}(x_{2jt}, y_{it} \mid j \neq 0)$"		Yes	23.8	6.3	−0.6	−0.1
"$\mathbb{E}[x_{2jt} \mid y_{it} < \bar{y}_t, j \neq 0]$"			62.7	17.3	0.9	1.0
"$\mathbb{E}[x_{2jt} \mid y_{it} < \bar{y}_t, j \neq 0]$"		Yes	24.1	6.4	−0.5	−0.4
"$\mathbb{E}[x_{2jt} \mid \tilde{y}_{it} < \bar{y}_t, j \neq 0]$"	Yes		64.4	18.0	0.8	0.7
"$\mathbb{E}[x_{2jt} \mid \tilde{y}_{it} < \bar{y}_t, j \neq 0]$"	Yes	Yes	107.1	19.1	104.6	−13.7

This table reports median absolute error (MAE) and median bias of parameter estimates over 1,000 simulated datasets for standard and optimal micro moments. The first and third rows are the same as the fourth and sixth rows in Table 5. The second and fourth rows use these same standard micro moments in the first GMM step to construct optimal micro moments for the second step. For the last two rows, we simulate a second, independent micro dataset that is configured the same, except we replace y_{it} with $\tilde{y}_{it}$: the 25th percentile of income if below the median or the 75th percentile if above. We use this second dataset for "$\mathbb{E}[x_{2jt} \mid \tilde{y}_{it} < \bar{y}_t, j \neq 0]$" and in the last row, optimal micro moments as well.

for measuring the informativeness of moments for parameter estimates. We make computing these straightforward with PyBLP.[70] For example, in the last row of Table 5, a 1% decrease in the asymptotic variance of "$\mathbb{C}(x_{2jt}, y_{it} \mid j \neq 0)$" is associated with 5.1% and 5.5% decreases in those of $\hat{\pi}_1$ and $\hat{\pi}_x$, respectively, but the same elasticities are only around 0.004% for "$\mathbb{E}[x_{2jt} \mid y_{it} < \bar{y}_t, j \neq 0]$".[71] As we would expect, the additional moment provides little additional informativeness beyond the covariance.

Optimal micro moments and compatibility

In Table 6 we illustrate the performance of optimal micro moments. The first row is the same as the fourth row in Table 5. In the second row, we use these same standard moments to obtain a first-stage estimator, and in the second GMM step, use optimal micro moments that match scores of π_1 and π_x. This requires using the full micro dataset rather than two summary statistics, but it does, unsurprisingly, decrease the variance of the estimator. In the middle two rows, we use the slightly less-informative micro moment "$\mathbb{E}[x_{2jt} \mid y_{it} < \bar{y}_t, j \neq 0]$" in the sixth row of Table 5. When using this as a first-stage estimator, the finite sample performance of the optimal micro moments is slightly worse, although not by much.

In the last two rows, we illustrate an example where the "optimal micro moments" can perform worse than matching simple summary statistics. We simulate a second, independent micro dataset that is configured the same as the first, except we replace income y_{it} with a censored version $\tilde{y}_{it}$, an indicator for whether an individual is above or below the median income $\bar{y}_t$. These new micro data $(t_n, j_n, \tilde{y}_{i_n t_n})$ are not "complete" in the sense that they do not contain all of the information necessary to compute the individual choice probabilities (which require the actual income y_{it}). To approximate what a researcher might do here, when computing the scores we replace $\tilde{y}_{it}$ with the 25th percentile of income if below the median or the 75th percentile if above. As we see in the last row of Table 6, the optimal micro moments from the incompatible micro dataset perform significantly worse than no micro moments at all, particularly for $\hat{\pi}_1$. Adding micro statistics of the form "$\mathbb{E}[x_{2jt} \mid \tilde{y}_{it} < \bar{y}_t, j \neq 0]$" contains relevant information and does not have the same compatibility problems, giving similar improvements as before.

While we focus on changing the set of moments to address the compatibility problem, an alternative would be to modify the model to match the observed moments. One option might be to consider two sets of coefficients (π_h, π_l), for high- and low-income individuals. This would eliminate the compatibility problem and allow us to use the scores.[72]

Pooling markets

Often, a researcher may have the same type of micro statistic for different markets. A practical question is whether one should pool these into a single micro moment,[73] or match a separate micro moment for each market. Computationally, pooling is not particularly important, since micro values v_{pijt} will still need to be computed in each market. Statistically, however, we should expect market-specific moments to contain more information, reducing the variance of the estimator.

However, it is well-known that adding many moment conditions asymptotically biases the standard GMM estimator (Han and Phillips, 2006; Newey and Windmeijer, 2009). In Fig. 2 we illustrate this bias–variance tradeoff. From left to right, we increase the number of micro moments, pooling them across a decreasing number of markets. This reduces the variance of the estimator at

---

[70] The ingredients are estimates of the asymptotic covariance matrices of the parameter estimates and moments, along with the moments' Jacobian. These ingredients, along with the sensitivity measure of Andrews et al. (2017), are automatically reported by PyBLP.

[71] These numbers are medians over 1,000 simulated datasets of the $\mathcal{E}_3$ measure from Honore et al. (2020). The corresponding elasticities for "$\mathbb{E}[y_{it} \mid j \neq 0]$" are 6.60% and 6.56% for $\hat{\pi}_1$ and $\hat{\pi}_x$, respectively.

[72] Strictly speaking, without changing the data generating process, this model would be misspecified so we omit it from Table 6.

[73] Given summary statistics $\bar{v}_t$ each based on N_t observations, the pooled summary statistic would be $\sum_t N_t \cdot \bar{v}_t / \sum_t N_t$.
C. Conlon and J. Gortmaker

Fig. 2. Pooling markets.

This figure reports median absolute error (MAE) and median bias of parameter estimates over 1,000 simulated datasets for an increasing number of micro moments that are pooled across a decreasing number of markets. On the left, we match the same $M_M = 2$ micro moments "$\mathbb{E}[y_{it} \mid j \neq 0]$" and "$\mathbb{C}(x_{2jt}, y_{it} \mid j \neq 0)$" in the fourth row of Table 5, which are pooled across all $T = 40$ markets. On the right, we match $M_M = 80$ micro moments "$\mathbb{E}[y_{it} \mid j \neq 0, t]$" and "$\mathbb{C}(x_{2jt}, y_{it} \mid j \neq 0, t)$", one for each market t. In the middle, we pool moments across decreasing numbers of markets (factors of the full 40). We do not use any observables to select which markets to pool for each micro moments. The top panel reports results for $\hat{\pi}_1$; the bottom, for $\hat{\pi}_x$.

the cost of some bias. In general, we prefer more micro moments to fewer, particularly if markets are very observably different, since this will reduce the variance of the estimator. However, much like adding many instruments to simple linear IV regressions can be problematic (see, e.g., Angrist et al., 1999), it is important to be aware of bias or lack of interpretability that one might be introducing by adding a large number of moments.

Numerical integration

In Table 7 we consider another important choice: how to choose sets of consumer types $\mathcal{I}_t$ to numerically integrate over a population of consumers. In Conlon and Gortmaker (2020) we emphasize how bounded and continuously differentiable integrals for market shares can be well-approximated with a small number of quadrature nodes and weights.[74] In the first two rows of Table 7 we compare $|\mathcal{I}_t| = 7$ Gauss–Hermite quadrature nodes with $|\mathcal{I}_t| = 1{,}000$ Monte Carlo draws from the true distribution of income y_{it}. Statistical performance is comparable, but with quadrature, it takes two orders of magnitude less time to compute the estimator.[75]

In the bottom two rows, we provide a typical example for which quadrature should not be used. Instead of matching a "$\mathbb{C}(x_{2jt}, y_{it} \mid j \neq 0)$" moment, which is continuously differentiable in income y_{it}, we match "$\mathbb{E}[x_{2jt} \mid y_{it} < \bar{y}_t, j \neq 0]$", which is not because of the low-income indicator. As already discussed, discretizing income discards information, so the estimator performs worse regardless of the integration rule. But more importantly, since quadrature rules are specific to the domain of integration (e.g., a normal density over $\mathbb{R}$), they will not correctly integrate sub-intervals. This becomes apparent in Table 7. Other than not using quadrature in these cases, there are no obvious solutions when computing s_{jt} requires integrating over the entire distribution

---

[74] Theoretically, the integrand is approximated with a polynomial and then integrated exactly.

[75] For more dimensions of integration – more demographics or unobserved preferences – this computational performance gap decreases, and quadrature, including more sophisticated sparse grids, becomes comparable to Monte Carlo methods. See Figure 1 in Conlon and Gortmaker (2020).

Table 7
Numerical integration.

Micro moments (plus "$\mathbb{E}[y_{it} \mid j \neq 0]$")	Integration	MAE (%)		Bias (%)	
		$\hat{\pi}_1$	$\hat{\pi}_x$	$\hat{\pi}_1$	$\hat{\pi}_x$
"$\mathbb{C}(x_{2jt}, y_{it} \mid j \neq 0)$"	Quadrature	31.6	9.2	−1.9	−1.1
"$\mathbb{C}(x_{2jt}, y_{it} \mid j \neq 0)$"	Monte Carlo	34.0	10.8	4.1	1.1
"$\mathbb{E}[x_{2jt} \mid y_{it} < \bar{y}_t, j \neq 0]$"	Quadrature	251.8	71.0	24.6	5.4
"$\mathbb{E}[x_{2jt} \mid y_{it} < \bar{y}_t, j \neq 0]$"	Monte Carlo	62.7	17.3	0.9	1.0

This table reports median absolute error (MAE) and median bias of parameter estimates over 1,000 simulated datasets for different choices of consumer types $\mathcal{I}_t$ for numerically integrating over the lognormal population distribution of income y_{it}. "Quadrature" refers to $|\mathcal{I}_t| = 7$ Gauss–Hermite nodes and weights that exactly integrate polynomials of degree $2 \times 7 - 1 = 13$ or less. Quadrature nodes are transformed into nodes for income with the mean and standard deviation of log income in each market. "Monte Carlo" refers to $|\mathcal{I}_t| = 1,000$ pseudo-Monte Carlo draws from the true distribution of income. The cutoff $\bar{y}_t$ is the median income y_{it} in market t.

and the micro moments require integration over a sub-interval.

Problem scaling

In Section 4 and Appendix E we discuss the econometric properties of the micro BLP estimator under different asymptotic thought experiments: (a) many markets, including those covered by surveys; (b) many markets, few with surveys, but the surveys are large; and (c) few markets, but markets and surveys are both large. Still using "$\mathbb{E}[y_{it} \mid j \neq 0]$" and "$\mathbb{C}(x_{2jt}, y_{it} \mid j \neq 0)$" micro moments, in Fig. 3 we use our simulations to illustrate that the estimator seems to have desirable asymptotic properties that translate to finite samples. From left to right, each column corresponds to cases (a), (b), and (c), respectively. For all cases, the variance of the estimator decreases similarly as we increase the number of aggregate and micro observations. In Appendix I we document that standard error estimators have good coverage and low bias in finite samples, reflecting the asymptotic normality of the estimator.

Unobserved heterogeneity

So far, our simulations only model one source of observed heterogeneity: income. To discuss the role of unobserved heterogeneity, we draw unobserved preferences ν_{2it} for x_{2jt} from the standard normal distribution and use 1,000 scrambled Halton draws (Owen, 2017) to approximate this distribution during estimation. We then add a $\sigma_x x_{2jt} \nu_{2it}$ term to heterogeneous utility, and choose σ_x to make unobserved preferences fairly important:

$$\mu_{ijt} = \pi_1 y_{it} + \pi_x x_{2jt} y_{it} + \sigma_x x_{2jt} \nu_{2it}, \quad \begin{aligned} \Pi_0 &= (\pi_{01}, \pi_{0x}, 0)' = (-0.1, 0.1, 0)', \\ \Sigma_0 &= \text{diag}(0, \sigma_{0x}, 0) = \text{diag}(0, 0.5, 0). \end{aligned} \tag{30}$$

In Table 8 we illustrate how the standard "$\mathbb{E}[y_{it} \mid j \neq 0]$" and "$\mathbb{C}(x_{2jt}, y_{it} \mid j \neq 0)$" moments still greatly improve the performance of the estimator. Optimal micro moments do even better.

Our default configuration has a great deal of cross-market variation in choice sets $\mathcal{J}_t$, including the number of products $|\mathcal{J}_t|$ and the values of product characteristics (x_{jt}, ξ_{jt}). This is precisely the type of aggregate variation that is needed to identify Σ (Berry and Haile, 2014). As a result, particularly because we are using optimal instruments, $\hat{\sigma}_x$ has very low bias and variance, even without any micro moments.

In the bottom three rows, we use the same choice set $\mathcal{J}_t = \mathcal{J}$ in each market. Even with optimal instruments, $\hat{\sigma}_x$ has a substantial amount of bias and variance, and including micro data that link demographics to choices does not particularly improve the performance of $\hat{\sigma}_x$. This illustrates an important insight of Berry et al. (2004a) that is formalized nonparametrically by Berry and Haile (2024): cross-market choice set variation is still needed to nonparametrically identify Σ, even when using within-market variation that links demographics to choices.[76]

Second choices

Some datasets will simply not exhibit much cross-market choice set variation, either because there is only a single or a few markets, or because product offerings are fairly uniform. An alternative is using second choice data. Intuitively, each second choice observation is similar to observing a counterfactual market in which the consumer's first choice is removed from the choice set.

In Table 9 we illustrate the benefits from second choice data for our configuration with no choice set variation. In addition to the main micro dataset, we simulate a second, independent micro dataset that conditions on inside choices as well, but also reports second choices.

---

[76] In our simulations, identification of Π comes from both within- and cross-market variation in demographics, as well as our parametric assumptions about how demographics enter into utility.
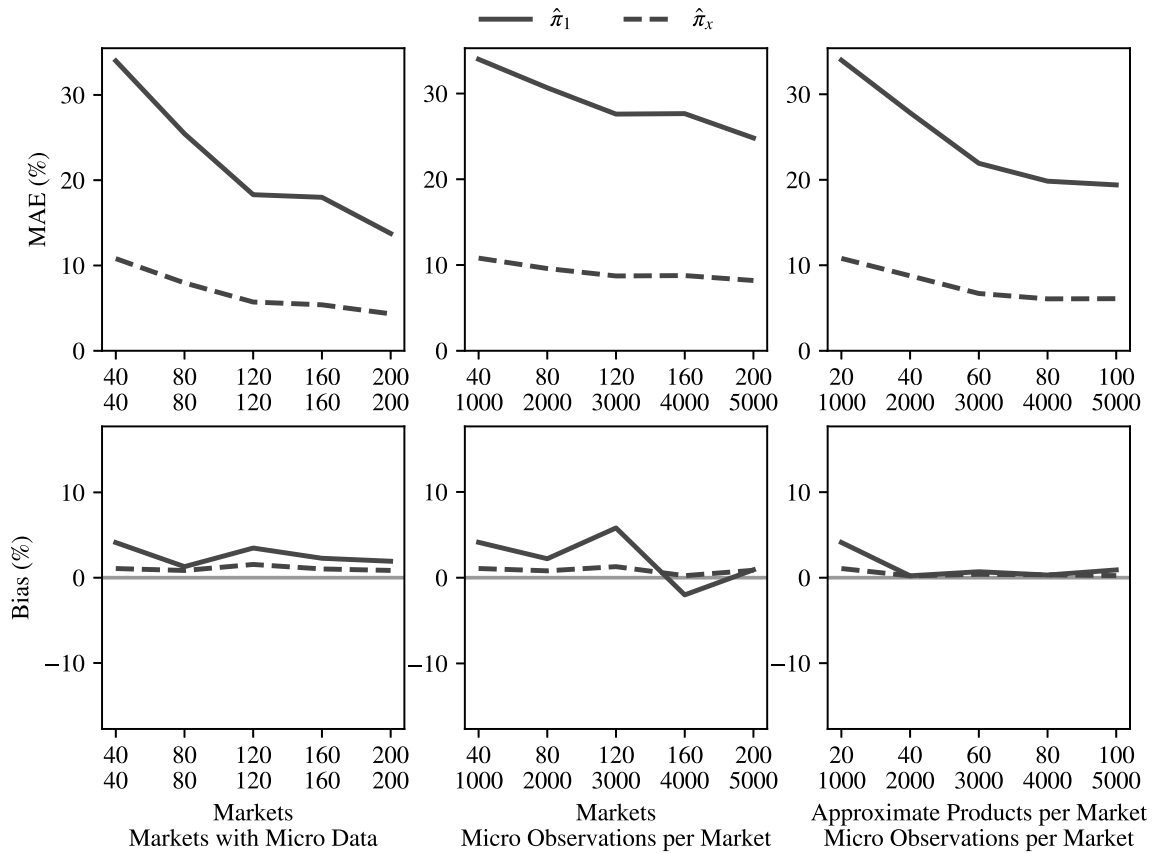

Fig. 3. Problem scaling.
This figure reports median absolute error (MAE) and median bias of parameter estimates over 1,000 simulated datasets as finite sample sizes approach the three asymptotic thought experiments discussed in Appendix E. In all panels we match the same "$\mathbb{E}[y_{it} \mid j \neq 0]$" and "$\mathbb{C}(x_{2jt}, y_{it} \mid j \neq 0)$" moments in the fourth row of Table 5. The leftmost panel fixes the number of products and micro observations per market and scales up the number of markets, including those with micro data. The middle panel fixes the number of products per market and the number of markets with micro data and scales up the number of aggregate markets and the number of micro observations in each of the fixed number of markets. The rightmost panel fixes the number of markets and scales up the number of products and micro observations per market.

Table 8
Unobserved heterogeneity.

Micro moments shorthand	$J_t = J$	Optimal	MAE (%)			Bias (%)		
			$\hat{\pi}_1$	$\hat{\pi}_x$	$\hat{\sigma}_x$	$\hat{\pi}_1$	$\hat{\pi}_x$	$\hat{\sigma}_x$
No Micro Moments			225.7	76.5	3.4	−43.4	−14.6	−0.3
"$\mathbb{E}[y_{it} \mid j \neq 0]$, $\mathbb{C}(x_{2jt}, y_{it} \mid j \neq 0)$"			39.2	12.1	3.2	3.3	0.1	−0.3
"$\mathbb{E}[y_{it} \mid j \neq 0]$, $\mathbb{C}(x_{2jt}, y_{it} \mid j \neq 0)$"		Yes	29.1	8.3	3.3	−2.8	−0.7	−0.3
No Micro Moments	Yes		153.6	79.3	99.5	2.8	21.9	31.8
"$\mathbb{E}[y_{it} \mid j \neq 0]$, $\mathbb{C}(x_{2jt}, y_{it} \mid j \neq 0)$"	Yes		33.6	23.1	94.0	−0.8	−13.8	−82.3
"$\mathbb{E}[y_{it} \mid j \neq 0]$, $\mathbb{C}(x_{2jt}, y_{it} \mid j \neq 0)$"	Yes	Yes	31.8	24.0	99.2	−5.5	−17.9	−86.4

This table reports median absolute error (MAE) and median bias of parameter estimates over 1,000 simulated datasets with unobserved preferences for different amounts of choice set variation and different micro moments. We draw unobserved preferences v_{2it} from the standard normal distribution and add $\sigma_x x_{2jt} v_{2it}$ to μ_{ijt} with the true $\sigma_{0x} = 0.5$. In the bottom three rows, we use the same choice set $J_t = J$ in each market, cluster our estimates of the asymptotic covariance matrix for ξ_{jt} by product j, and use the number of markets T as the number of aggregate observations N_A.

Matching the covariance "$\mathbb{C}(x_{2jt}, x_{2k(-j)t} \mid j, k \neq 0)$" between the exogenous product characteristic for first and second choices greatly reduces the variance of $\hat{\sigma}_x$. Matching the sum "$\mathbb{E}[x_{2jt} + x_{2k(-j)t} \mid j, k \neq 0]$", which is closer to the score for σ_x in Eq. (26), reduces the variance even more. Fig. 4 reports a correlation matrix between micro values v_{pijkt} underlying these moments and the score for σ_x. Since $x_{2jt} \cdot x_{2k(-j)t}$ and $x_{2jt} + x_{2k(-j)t}$ are highly correlated with one another, their correlations with the score are similar.

Table 9
Second choices.

Micro Moments (plus "$\mathbb{E}[y_{it} \mid j \neq 0]$, $\mathbb{C}(x_{2jt}, y_{it} \mid j \neq 0)$")	Optimal	MAE (%)			Bias (%)		
		$\hat{\pi}_1$	$\hat{\pi}_x$	$\hat{\sigma}_x$	$\hat{\pi}_1$	$\hat{\pi}_x$	$\hat{\sigma}_x$
No Second Choice Moments		33.2	23.2	94.4	−0.9	−14.0	−82.7
"$\mathbb{C}(x_{2jt}, x_{2k(-j)t} \mid j, k \neq 0)$"		33.9	12.0	16.4	3.7	0.3	−2.3
"$\mathbb{E}[x_{2jt} + x_{2k(-j)t} \mid j, k \neq 0]$"		34.0	10.4	5.3	4.4	1.7	−0.5
"$\mathbb{P}(x_{2k(-j)t} < \overline{x}_{2t} \mid x_{2jt} \gtreqless \overline{x}_{2t}, j, k \neq 0)$"		34.7	11.0	12.5	3.5	1.9	−2.9
"$\mathbb{P}(x_{2k(-j)t} < \overline{x}_{2t} \mid x_{2jt} \gtreqless \overline{x}_{2t}, j, k \neq 0)$"	Yes	16.9	4.8	4.3	−0.3	−0.8	−1.0

This table reports median absolute error (MAE) and median bias of parameter estimates over 1,000 simulated datasets with unobserved preferences for different micro moments based on second choice data. We draw unobserved preferences v_{2it} from the standard normal distribution and add $\sigma_x x_{2jt} v_{it}$ to μ_{ijt} with the true $\sigma_{0x} = 0.5$. To eliminate cross-market choice set variation, we use the same choice set $\mathcal{J}_t = \mathcal{J}$ in each market, cluster our estimates of the asymptotic covariance matrix for ξ_{jt} by product j, and use the number of markets T as the number of aggregate observations N_A. In addition to the main micro dataset, we simulate a second, independent micro dataset that is configured the same, except that it also reports second choices. The shorthand "$\mathbb{P}(x_{2k(-j)t} < \overline{x}_{2t} \mid x_{2jt} \gtreqless \overline{x}_{2t}, j, k \neq 0)$" refers to two moments that match the share of individuals who divert from a below- or above-median x_{2jt} first choice j to a below-median x_{2kt} second choice k.

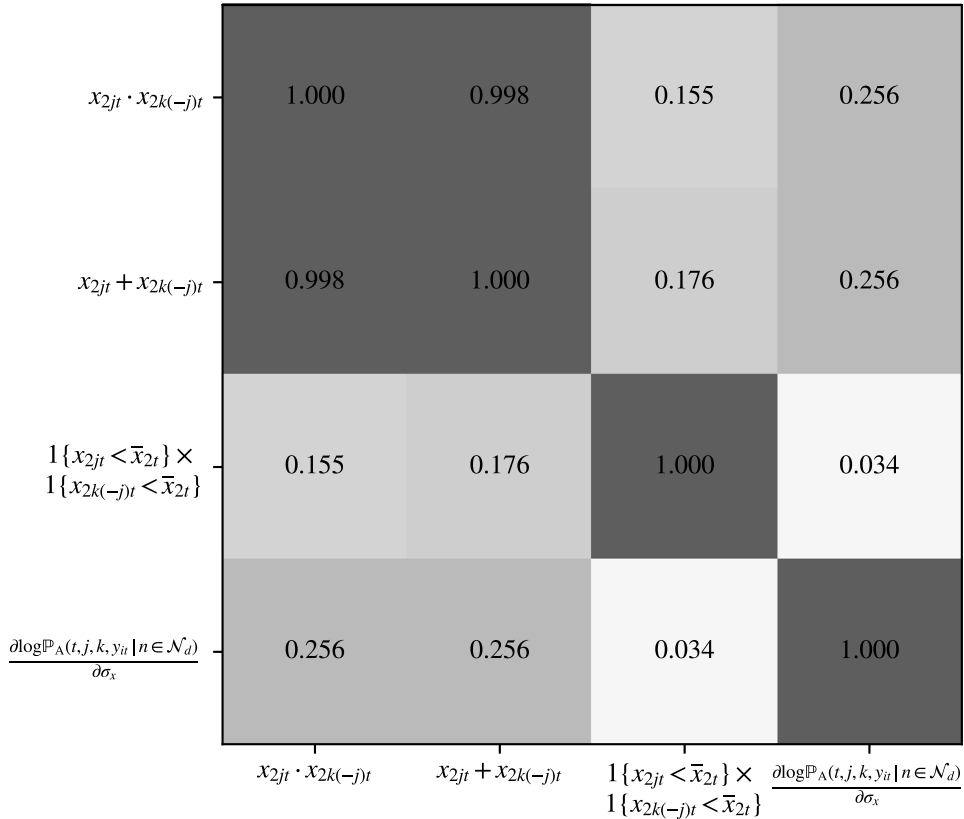

Fig. 4. Second choice micro moment correlations.
This figure reports median absolute correlations between different micro statistics over 1,000 simulated micro datasets underlying the second choice moments in Table 9. For each micro observation n in market $t_n = t$ of type $i_n = i$ with choices $j_n = j$ and $k_n = k$, we compute four statistics: $x_{2jt} \cdot x_{2k(-j)t}$ captures variation in "$\mathbb{C}(x_{2jt}, x_{2k(-j)t} \mid j, k \neq 0)$" moments, $x_{2jt} + x_{2k(-j)t}$ captures variation in "$\mathbb{E}[x_{2jt} + x_{2k(-j)t} \mid j, k \neq 0]$" moments, $1\{x_{2jt} < \overline{x}_{2t}\} \cdot 1\{x_{2k(-j)t} < \overline{x}_{2t}\}$ captures variation in "$\mathbb{P}(x_{2k(-j)t} < \overline{x}_{2t} \mid x_{2jt} < \overline{x}_{2t}, j, k \neq 0)$" moments, and $\partial \log \mathbb{P}_A(t, j, k, y_{it} \mid n \in \mathcal{N}_d) / \partial \sigma_x$ is the score for σ_x at the true θ_0.

We also consider matching the share of consumers who divert from a low- or high-x_{2jt} first choice j to a low-x_{2kt} second choice k. The hope is that this type of diversion ratio is easier to measure or more likely to be collected than the covariance. Discretizing x_{2jt} in this way reduces the correlation of each individual diversion ratio with the score, but in our simulations, matching only two diversion ratios is comparable in terms of variance reduction with the standard "$\mathbb{C}(x_{2jt}, x_{2k(-j)t} \mid j, k \neq 0)$" moment.

If the full second choice micro data are available, we can do even better. In the bottom row of Table 9 we show that the estimator is further improved when we use optimal micro moments that for the second GMM step match the scores of π_1, π_x, and σ_x.

8. Predicting substitution from seattle's sweetened beverage tax

Finally, we provide an empirical example to illustrate how to use micro moments with real data. Appendix D provides a second example, replicating the results in Petrin (2002) with PyBLP.

In recent years, one of the most used sources of matched aggregate and micro data for consumer purchases in the US are the NielsenIQ Retailer Scanner and Consumer Panel datasets as provided by the Kilts Center at the Chicago Booth School of Business. The scanner data contains product characteristics and weekly sales for a large sample of retailers across the US. The consumer data contains consumer demographics and purchase decisions for a large sample of participating US households.

To demonstrate how to use micro moments with NielsenIQ data, we estimate pre-2017 demand for soft drinks in Seattle. We then predict what would happen if prices increased by how much they did after the 2018 implementation of Seattle's sweetened beverage tax (SBT) – the most recent SBT implemented in the US – and compare our substitution estimates to what actually happened. We view this exercise as in-between answering a policy question and a Monte Carlo, since we are using real data but already know what happened. This type of exercise could be repeated for different cities to evaluate the potential effects of proposed taxes.[77]

In Appendix K we discuss all the decisions we make when constructing our data: market definition, demographic data, product data, instruments, market sizes, micro data, and a custom second choice survey. We also discuss other decisions we could have made, weighing their pros and cons. We hope Appendix K will be particularly helpful for researchers using NielsenIQ data or collecting second choice data to estimate their own demand systems.

We collect quarterly sales data from 2007 to 2016 on 2,672 soft drink UPCs sold at five large retailers in Seattle, for a total of $N_A = 78{,}161$ product-retailers.[78] In each quarter t, the market share S_{jt} of product-retailer j is total ounces purchased divided by the market size $\mathcal{M}_t$. To compute market sizes, we estimate of the number of trips made to these retailers and scale this by a maximum potential demand per trip of 720 ounces.[79] Later in this section we will discuss how such market size assumptions can affect estimates.

Our product characteristics x_{jt} are price and indicators for diet and small-sized drinks.[80] We use a Hausman (1996)-type instrument for prices (contemporaneous prices in cities other than Seattle) that is very similar to the one used by Allcott et al. (2019) and construct a Gandhi and Houde (2020)-style differentiation IV to identify the standard deviation of normally distributed unobserved preference heterogeneity for price.[81]

We report aggregate BLP estimates in the first column of Table 10. We include product-retailer and retailer-quarter fixed effects to account for product-specific preferences and time-varying demand for retailers. We cluster standard errors by brand $b(j)$. Across specifications, our estimated price elasticity of demand is around -1.3, which is on the high end of typical estimates in the existing literature between -0.8 and -1.4 (e.g., Powell et al., 2013).

We also report results from our counterfactual in which we increase the prices of taxed 2016 products by how much they seemed to have increased after the introduction of the 2018 SBT of 1.75 cents per ounce:[82] 1.15 cents for taxed small-sized drinks and 0.97 cents for taxed family-sized ones (Powell and Leider, 2020).[83] We use a manual classification of taxed and untaxed goods that was created and graciously provided to us by the authors and research team of Powell and Leider (2020). Although the Seattle tax excluded diet beverages, tax status is not one-to-one with our diet indicator, with a strong but imperfect correlation of -0.76 in our 2016 data. Our estimates of a decrease in taxed ounces purchased of -30% and a small increase in untaxed ounces of 1% are not too far from the -22% and 4% estimated by Powell and Leider (2020), but as we discuss below, could benefit from additional dimensions of preference heterogeneity.

The political discourse surrounding SBTs and related economic theory emphasizes their differential effects by income (see, e.g., Allcott et al., 2019; Conlon et al., 2024). To predict differential substitution by income group, we include an indicator in demographics y_{it} for households with income above the 2016 median in Washington. We also include an indicator for households with at least one child.[84] We construct demographic shares for each of the four bins from annual American Community Survey (ACS) data for Seattle, and re-weight NielsenIQ households in Seattle by these ACS shares.

---

[77] Similarly, Zhen et al. (2014) estimate an Exact Affine Stone Index (EASI) demand model (Lewbel and Pendakur, 2009) that includes 23 different categories related to soft drinks to evaluate the impact of SBTs. EASI is a product space approach to demand estimation, which we view as complementary to characteristics space approaches like BLP.

[78] This includes fruit drinks and diet drinks, but for simplicity we do not consider juice or other sugary product categories. We combine product-retailers in the bottom 5% of ounces sold with the outside good in each quarter.

[79] We have an in-depth discussion of market sizes and how we form these estimates in Appendix K.

[80] Following Powell and Leider (2020), we define small- or individual-sized products as single-unit beverages that are no more than one liter in volume. Diet classification is in Appendix K, and is particularly important for this setting because the Seattle tax excluded diet drinks. A more in-depth study of soft drink demand would incorporate random coefficients on more characteristics.

[81] As we discuss below, we do not attempt to identify the distributions of random coefficients on other diet and small-sized indicators with only aggregate data because along these dimensions, cross-quarter choice set variation is very limited.

[82] Although modeling the supply side and predicting passthrough is beyond the scope of this paper, doing so would be useful for informing SBT policy. For example, O'Connell and Smith (2024) use simulated maximum likelihood to estimate a similar demand model for soft drinks in the UK and study how market power affects passthrough. In their Appendix E, they conduct a similar validation exercise for the supply side, comparing their predicted passthrough estimates with those that actually occurred following a UK SBT in 2018.

[83] Powell and Leider (2020) estimate these passthrough rates of 66% and 55% with a differences-in-differences approach, using Portland as the control group. They also use NielsenIQ scanner data.

[84] We limit our attention to two binary demographics for simplicity in this empirical example. A more in-depth study would incorporate more functions of demographics measured in Census and NielsenIQ data.

		(0.064)	(1.540)	(1.955)

This table reports results for the empirical example described in Section 8. From left to right, we report estimates using aggregate moments, adding standard micro moments, adding second choice moments, and replacing standard micro moments with the optimal micro moments described in Section 6. Standard errors are clustered by brand for the aggregate moments and are in parentheses; we compute those for tax counterfactual with a parametric bootstrap.

Since at the city level these demographics vary little during our sample period,[85] we do not attempt to identify how preferences vary by demographic group with only cross-market variation.[86] Indeed, following our advice from Section 3, running the approximate regression from Salanié and Wolak (2022) gives very noisy point estimates for Π. This is unsurprising because such estimates are essentially formed from $2016 - 2007 = 9$ observations.

Instead, we match two sets of standard micro moments: "$\mathbb{E}[y_{rit} \mid j \neq 0]$" and "$\mathbb{C}(x_{cjt}, y_{rit} \mid j \neq 0)$" for the $R = 2$ demographics and $C = 3$ characteristics. We use the Consumer Panel data and compute $m = 1, \ldots, M_M = 8$ micro moment sample values $f_m(\overline{v})$ from a sample of $N_d = 10{,}455$ grocery trips with an inside purchase $j \neq 0$.[87]

The second column of Table 10 reports micro BLP estimates. We estimate a slight decline of price sensitivity with income,[88] and households with children also tend to be more price sensitive. Both low income households and those with children tend to dislike diet drinks. Incorporating micro data allows us to predict how the tax counterfactual differentially affects consumers by demographic group. Slightly more elastic demand for households with low income or children results in slightly more substitution away from taxed goods. However, compared to a baseline reduction in taxed volume of 30%, we are able to reject predicted differences of more than 4 percentage points for low versus high income households and 7 percentage points for households with versus without children at a 5% significance level.

These predictions are generally in-line with those of Barker et al. (2022), who pool 529 households in the NielsenIQ Consumer Panel dataset together with data before and after the implementation of seven recent SBTs in the US between 2015 (Berkeley) and 2018 (Seattle), and struggle to find statistically significant differences in the impact of these taxes by income group and presence of children. We view a structural approach that incorporates micro data as complementary to approaches such as that of Barker et al. (2022), which makes different modeling assumptions but can be limited by small sample sizes.[89]

Incorporating demographics captures some heterogeneous preferences for the outside good and diet beverages. But the model is missing a great deal of potential unobserved heterogeneity. Unfortunately, with market fixed effects, the distribution of unobserved preferences for the outside good is not identified with only aggregate data,[90] and we find that cross-quarter aggregate variation in the number of diet drinks is also insufficient to precisely estimate the scale of unobserved preferences for diet drinks.

Instead, we use survey-based second choice data.[91] To demonstrate how researchers can run a second choice survey, we use Prolific Academic to recruit 100 participants who live in Washington State for an online survey.[92] Our survey design is similar to that used for choice-based conjoint analysis (e.g., Allenby et al., 2019), and we provide more details at the end of Appendix K, including discussion of potential biases that often show up in results from online surveys. We use the survey to compute two diversion ratios: the share of participants who would divert to the outside good or a diet soft drink if their first choice non-diet brand were unavailable.[93] Like in the NielsenIQ micro data, we weight observations by ounces typically purchased and adjust for

---

[85] The share of high income households increases from 35% in 2007 to only 40% in 2016. The share of households with at least one child increases from 10% to only 11%.

[86] If we try to do so by including instruments that interact moments of the demographic distribution with characteristics and differentiation IVs, we get very noisy estimates that severely corrupt our other estimates.

[87] We compute weighted averages and covariances to account for both non-random participation of households in the NielsenIQ panel and different numbers of total grocery trips per quarter. See Appendix K for more details.

[88] An unconditional negative covariance in the micro data between prices and high income is potentially misleading. High income households also tend to purchase cheaper family-sized products. This negative covariance switches sign after controlling for package size.

[89] One country with much larger sample sizes for studying the impact of SBTs is the UK, through data collected by the National Child Measurement Programme (see, e.g., Rogers et al., 2023).

[90] Recalling the FRAC intuition from Section 3, the artificial regressor on a constant $x_{jt} = 1$ is $a_{jt} = s_{0t} - 1/2$, variation of which is absorbed by market t fixed effects.

[91] Another approach would be to compute first- and seconds shares from a single household's purchases over time in the NielsenIQ micro data. The validity of this approach will depend on what generated changes in product availability or characteristics that led to switching. Since we generally expect product availability to be correlated across products, we prefer self-reported second choices, but observational diversion can be useful in settings where survey data is unavailable or unreliable.

[92] A larger sample size would be appropriate for a more complete empirical study. Allenby et al. (2019) notes that many conjoint practitioners use sample sizes of 500 to 1,000.

[93] We increase the total number of survey participants to 139 until we get 100 participants who say they have purchased at least one of eight of the most popular non-diet brands in Seattle during the last 30 days: Coke, Pepsi, Gatorade, Powerade, Canada Dry, Dr Pepper, Mountain Dew, or Seven Up.

non-random sampling by demographic group.

In the third column of Table 10, we match these two diversion statistics for the last quarter in our sample.[94] If respondents' non-diet first choice soft drink brand were unavailable, "$\mathbb{P}(\text{Diet}_{k(-b(j))t} \mid \text{Surveyed Non-diet}_{jt}) = 16\%$" of respondents said they would divert to a diet beverage, and "$\mathbb{P}(k(-b(j)) = 0 \mid \text{Surveyed Non-diet}_{jt}) = 17\%$" said they would divert to the outside good, which includes both non-soft drinks and no beverage. Without matching these two additional moments, the model predicts 92% and 3%, respectively, suggesting that there is a great deal of unobserved preference heterogeneity left unmodeled.

Indeed, we get large estimated standard deviations on normally distributed unobserved preferences for inside goods and the diet characteristic. As a result, the counterfactual predicts a smaller decrease in taxed volume purchased, −16%, somewhat undershooting the estimate of −22% in Powell and Leider (2020), and a larger increase in untaxed volume purchased, 9%, somewhat overshooting but not statistically different from the estimate of 4% in Powell and Leider (2020). Given the nature of an imperfect prediction exercise, we do not expect to perfectly predict what actually happened, but do view our second choice estimates as more credible than those that rely more heavily on strong assumptions about substitution proportional to share and market size.

Finally, in the fourth column of Table 10, we replace the standard micro moments with optimal micro moments in the second GMM step. We do not replace our second choice moments because, as is often the case, our survey did not collect full micro data, only enough to compute our desired diversion ratios. Point estimates and counterfactual results are fairly similar, suggesting that most of the information in the NielsenIQ micro data is already spanned by the standard micro moments for this model. This should not be surprising because the model discretized observed heterogeneity into four types: high and low income, and with and without children. We provide more in-depth discussions of how to compute optimal micro moments with PyBLP at the end of Appendix F and how to do so with NielsenIQ micro data near the end of Appendix K.

There are a number of extensions that would improve a more complete policy exercise. Incorporating more product characteristics, more consumer demographics, and more second choice data would help to better explain substitution patterns. Discussed in Appendix A, a lognormal random coefficient on price often provides a better fit, and can be helpful for modeling a supply side.[95] In Appendix B we discuss adding a nesting structure, which could be useful for explaining substitution between categorical characteristics such as brand or store. PyBLP also supports inclusion of product-specific demographics such as geographic distance to stores, which could allow researchers to predict cross-border shopping effects.[96]

9. Conclusion and practical advice

This article was motivated with a frustration experienced by many researchers with the aggregate BLP estimator: aggregate variation is usually very limited, leading to poor estimates of demand. Coupled with the recommended practices from Conlon and Gortmaker (2020) for the aggregate side of estimation, we confirm in this article that incorporating micro data can substantially improve the finite-sample performance of the BLP estimator. Our hope is that going forward, a standardized framework for doing so will encourage more researchers to use or collect micro data, particularly second choices, which can be very useful for estimating the degree of unobserved preference heterogeneity.

This article makes a number of contributions. Perhaps most importantly, we delineate a flexible econometric framework for incorporating many different types of micro data into BLP-style estimation, which we subject to a number of different asymptotic thought experiments. These include cases where we observe relatively complete data on individual choices, demographics, and characteristics, and cases where we observe only limited statistics from surveys of individuals. Characterizing the asymptotic covariance matrix also allows us to clarify that researchers do not need to observe sample covariances between micro summary statistics to do valid statistical inference. Finally, we contribute a characterization of the optimal micro moments in the spirit of Chamberlain (1987) and a computationally straightforward procedure for computing them, which can be done with only a few lines of code when using PyBLP. These have the advantage of not only reducing bias and increasing efficiency, but can also significantly reduce the overall dimension of the problem.

We also provide some practical tips to researchers. First, researchers can check how much cross-sectional (or time series) variation there is in the aggregate data using the FRAC estimator of Salanié and Wolak (2022). Second, researchers can measure how much of the variation in the (infeasible) optimal micro moments from the score contributions can be captured using their micro statistics, even if complete individual data is not available. Third, researchers should be mindful of compatibility issues across datasets. The marginal distribution of demographics like income, or the purchase probabilities of particular choices may vary significantly between aggregate and micro datasets. In this case, matching moments from micro datasets (including the "optimal micro moments") may be worse than using only aggregate data. However, we illustrate that alternative micro statistics can be designed to be more robust in this scenario. Fourth, while quadrature rules are often the best choice for evaluating numerical integrals of mixed logit models with aggregate data, most quadrature rules are not designed to accurately integrate sub-intervals; in this case, less accurate Monte Carlo rules may be preferred. Finally, researchers should think about which model parameters are most relevant for the policies they are interested in, and carefully consider designing surveys or experiments to help better estimate those objects. Here we provide a proof

---

[94] By matching statistics computed for Washington residents, not just Seattle residents, and for consumers in 2023, not 2016, we are assuming that these diversion ratios would not be much different for Seattle in 2016. At a minimum, in Appendix K we check whether the statistics are different for the 25% of respondents who live in Seattle and do find some difference for diversion to the outside good, although they are noisy.

[95] This guarantees downward sloping demand for all consumers, which can help guarantee pricing equilibrium existence and uniqueness and allow for more flexible pass-through (Miravete et al., 2023).

[96] We discuss adding geographic distance in more depth in Appendix K.

of concept showing how a small and inexpensive survey could be designed to better understand the effects of a sugary beverage tax.

Our goal has been to extend the recommended practices in Conlon and Gortmaker (2020) to the case with micro data, not only through this paper but also in a single software package, PyBLP. We have provided a list of recommended practices, evaluated them with simulations, and made them either defaults or easy to use in PyBLP. Our hope is that these practices can now be made available to a wider range of researchers. For researchers who wish to incorporate micro data into similar econometric frameworks that are not yet supported by PyBLP, we hope that the framework and results developed in this article, along with PyBLP's well-documented code, serve as a useful starting point.
